DOCK8 deficiency	*DOCK8*	Autosomal recessive	Low IgM, normal to high IgG and IgA, high IgE; poorly functioning Treg	Low NK cells with poor function, eosinophilia, recurrent infections, cutaneous viral, fungal, and staphylococcal infections, eczema and food allergy, virally driven cancers
DOCK2 deficiency	*DOCK2*	Autosomal recessive	Low lymphocyte numbers; defective T, B, and NK cells	Early-onset invasive bacterial and viral infections

CIITA = class II major histocompatibility complex transactivator; DOCK = dedicator of cytokinesis gene; IG = immunoglobulin; MHC = major histocompatibility complex; NK = natural killer; Nl = normal; *RFXANK* = regulatory factor X–associated ankyrin-containing protein; SCID = severe combined immunodeficiency; TAP = antigen peptide transporter; *TAPBP* = TAP binding protein; Treg = regulatory T cell; ZAP-70 = zeta-chain–associated protein kinase 70.

TABLE 231-3 EXAMPLES OF COMBINED DEFECTS OF IMMUNITY WITH SYNDROMIC FEATURES

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTIONS	DISEASE AND COMPLICATIONS
Wiskott-Aldrich syndrome	*WAS*	X-linked	Thrombocytopenia, small platelets, low IgM and poor antibody responses to polysaccharides	Impaired cell activation, mobility	Eczema, lymphoma, autoimmune disease, bacterial and viral infections
Ataxia-telangiectasia	*ATM*	Autosomal recessive	Some have IgA deficiency, IgG defects, lymphopenia in some, may have low T cells on newborn screening	Impaired DNA double-stranded break repair	Ataxia, telangiectasia, pulmonary infections, lymphoreticular and other malignant neoplasms, increased α-fetoprotein, x-ray sensitivity
DiGeorge/velocardiofacial syndrome/chromosome 22q11.2 deletion syndrome	22q11.2 deletion, rarely a deletion in 10p	De novo (majority) or autosomal dominant	Lymphopenia, low T-cell numbers, large deletion in chromosome 22 on fluorescence in situ hybridization	Impaired T-cell immunity	Cardiac abnormalities, hypoparathyroidism, abnormal facies
Hyper-IgE syndrome (Buckley-Job syndrome)	*STAT3*	Autosomal dominant	Eosinophilia, high IgE	Loss of normal cytokine activation, defective IL-17	Bacterial infections, eczema, distinctive facial features, osteoporosis, fractures, scoliosis, delay of shedding primary teeth, hyperextensible joints, candidiasis
Cartilage-hair hypoplasia	*RMRP*	Autosomal recessive	Lymphopenia, low T-cell numbers	Impaired processing of mitochondrial RNA	Short-limbed dwarfism, sparse hair, celiac disease, Hirschsprung disease, bone marrow failure, autoimmunity, susceptibility to lymphoma
Purine nucleoside phosphorylase (PNP) deficiency	*PNP*	Autosomal recessive	Progressive T-cell loss, immune globulins normal or low	Impaired T cell functions	Autoimmune hemolytic anemia, neurologic impairment

ATM = ataxia telangiectasia mutated; BCR = B-cell receptor; Ig = immunoglobulin; IL = interleukin; NEMO = NF-κB essential modulator; PNP = purine nucleoside phosphorylase; RMRP = RNA component of mitochondrial RNA processing endoribonuclease; STAT3 = signal transducer and activator of transcription 3; WASP= Wiskott-Aldrich protein.

PROGNOSIS

The prognosis in Wiskott-Aldrich syndrome is highly variable. Some individuals have mild thrombocytopenia and occasional nose bleeds, whereas other patients have inflammatory diseases or other complications that require additional, sometimes intensive, medical management.

ATAXIA-TELANGIECTASIA

EPIDEMIOLOGY AND PATHOBIOLOGY

Ataxia-telangiectasia is a rare neurodegenerative disease that leads to cerebellar atrophy, skin telangiectasia, and immune defects. Ataxia-telangiectasia is estimated to occur in 1 in 40,000 to 100,000 persons. Males and females are affected equally.

Ataxia-telangiectasia is due to recessive mutations in the gene that encodes the ataxia telangiectasia mutated protein (ATMp), which is important in both cell division and DNA repair. With the loss of ATMp, DNA breakage cannot be repaired, thereby leading to cell death.

CLINICAL MANIFESTATIONS

The clinical manifestations include progressive difficulty in walking, with ataxia beginning around age 5 years. Skin telangiectasias develop on the bulbar conjunctiva and behind the ears. The immune defects include IgA deficiency, IgG subclass defects, and cellular defects that can lead to recurring pulmonary infections and lung damage. Patients with ataxia-telangiectasia are radiosensitive and commonly develop lymphomas with increasing age.

DIAGNOSIS

The diagnosis of ataxia telangiectasia usually can be made by the characteristic clinical phenotype coupled with an increase in the serum α-fetoprotein blood level. Radiosensitivity can be assessed in vitro in fibroblast cell lines. Definitive diagnosis is by *ATM* gene sequencing.

TREATMENT AND PROGNOSIS

Treatment for ataxia-telangiectasia includes a medical team that can provide supportive measures and physical therapy as needed.[13] The life expectancy varies greatly, but most patients live into early adulthood.

DIGEORGE SYNDROME

EPIDEMIOLOGY AND PATHOBIOLOGY

DiGeorge syndrome is an autosomal dominant defect and one of the members of the 22q11.2 deletion syndrome that includes velocardiofacial syndrome, conotruncal anomaly face syndrome, congenital thymic aplasia, and thymic hypoplasia.[14] DiGeorge syndrome is one of the most common of the immune defects, with an estimated incidence of 1 : 4000. Both sexes are affected equally. The immune defect in DiGeorge syndrome varies widely, from complete loss of thymic development with no circulating T cells to normal T-cell numbers. In most cases, the thymus is hypoplastic.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Although it is classified as an immune defect because of thymic hypoplasia or aplasia, patients with DiGeorge syndrome are likely also to have congenital heart disease (Chapter 55), cleft palate or pharyngeal closure defects, characteristic facies, hypocalcemia due to parathyroid insufficiency, and learning disability. The more common cardiac defects include tetralogy of Fallot, interrupted aortic arch, ventricular septal defects, vascular rings, and anomalous return of brachial arteries. The mnemonic CATCH-22 has been applied: cardiac issues, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia. With loss of thymic tissue, cellular immunity is mildly to moderately impaired, leading to recurrent infections. Hypogammaglobulinemia is not uncommon and may be associated with autoimmune cytopenias, especially thrombocytopenia.

Infants with DiGeorge syndrome may be first identified on a newborn screen when poor thymic function leads to low T-cell receptor excision circles (TRECs). The diagnosis of DiGeorge syndrome can be confirmed on genetic testing with fluorescence in situ hybridization, which detects the loss of the 22q11.2 gene segment or, more rarely, a loss of 10p14-p13. However, about 10% of affected individuals do not have a gene defect but have the syndrome because of maternal diabetes, fetal alcohol syndrome, or prenatal exposure to isotretinoin.

TREATMENT

Treatment of DiGeorge syndrome is based on individual needs and may require cardiac surgery, repair of the cleft palate, and supplementation of calcium and vitamin D. Some patients are hypothyroid and require thyroid supplementation (Chapter 207). Whereas the level of T cells may be subnormal for age, sufficient T-cell function remains so that no specific treatment is needed (partial DiGeorge syndrome) because infections tend to be more related to anatomic abnormalities than T-cell hypofunction. If the thymus is totally absent, thymic transplantation can supply sufficient reconstitution.[15]

PROGNOSIS

For most patients, the prognosis depends on the concomitant medical issues, such as results of cardiac surgery, surgical repair of cleft palate, management of swallowing difficulties, and resources to enhance muscle strength and to overcome speech impediments and learning disabilities. For most patients, the T-cell defect is a minor component, and a near-normal lifespan is possible. With age, however, autoimmunity may become more prominent.

HYPERIMMUNOGLOBULIN E SYNDROME

EPIDEMIOLOGY AND PATHOBIOLOGY

Hyperimmunoglobulin E syndrome, also called Buckley-Job syndrome, is an immune deficiency syndrome characterized by eczema, skin and lung abscesses, hyperextensible joints, and recurrent bone fractures, distinctive coarse facies, eosinophilia, and high levels of serum IgE. The annual incidence is about 1 per million. Males and females are equally affected.

Hyperimmunoglobulin E syndrome is an autosomal dominant defect that results from mutations in the *STAT3* gene, which encodes a transcription factor, signal transducer, and activator of transcription 3. After activation by selected cytokines and growth factors, STAT3 protein is phosphorylated and translocated to the cell nucleus.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Characteristic clinical findings include eczema, recurrent skin boils, unusual facies with tubular nose, cyst-forming pneumonias often due to *S. aureus,* and increased serum IgE. Other common manifestations include a rash in the newborn period, mucocutaneous candidiasis, delayed shedding of primary teeth, and skeletal abnormalities, such as scoliosis, osteoporosis, and fractures with minimal trauma.

The diagnosis of hyperimmunoglobulin E syndrome can be strongly suspected on clinical grounds and an elevated hyperimmunoglobulin E level. Eosinophilia is common. The definitive diagnosis is best confirmed by identifying a *STAT3* or other mutation.

Features of the hyperimmunoglobulin E syndrome also have been found in a few patients with dominant negative mutations in *IL6ST,* which is a signaling receptor subunit of IL-6, and in patients with rare autosomal recessive defects in genes that encode tyrosine kinase 2 (Tyk2) and dedicator of cytokinesis 8 (DOCK8). In both of these conditions, however, viral infections are also prominent.[16]

TREATMENT

No definitive treatment exists for hyperimmunoglobulin E syndrome. Because of the propensity for staphylococcal infections, prophylaxis with appropriate antibiotics (e.g., trimethoprim-sulfamethoxazole, 2.5 mg/kg twice daily) is commonly used, along with oral antifungals such as itraconazole (100 mg daily for patients younger than age 13 years or weighing <50 kg; 200 mg daily for patients older than age 13 years or weighing >50 kg). Surgical drainage of abscesses is also important, but wound healing may be poor. Skin care for eczema may include bleach baths to reduce bacterial burden and antihistamines to control pruritus. Optimization of calcium and vitamin D levels may be useful to strengthen bones.

PROGNOSIS

Hyperimmunoglobulin E syndrome is a lifelong disease, and infections or other complications require individual care. With increasing age, worsening respiratory dysfunction is likely. Vascular and especially arterial abnormalities can occur. Many patients survive beyond age 50 years. The most common cause of death is infection.

CARTILAGE-HAIR HYPOPLASIA

EPIDEMIOLOGY AND PATHOBIOLOGY

Cartilage-hair hypoplasia is a rare autosomal recessive form of short-limbed dwarfism associated with a variable cellular immune deficiency. In the Old Order Amish population, cartilage-hair hypoplasia affects 1 in 1300 newborns. Among individuals of Finnish descent, the incidence is about 1 in 20,000.

The genetic defect in cartilage-hair hypoplasia is in the *RMRP* gene, which encodes the RNA in a mitochondrial RNA-processing endoribonuclease that helps copy mitochondrial DNA and process ribosomal RNA. In cartilage-hair hypoplasia, the encoded RNA is unstable.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Affected individuals have skeletal dysplasia, sparse hair, and a predominantly T-cell deficiency disease. The cellular defect is variable and ranges from mildly to severely impaired immunity. Other clinical features include short stature, anemia, autoimmunity, celiac disease, Hirschsprung disease, and several cancers, including lymphoma.

The diagnosis can be suspected by inheritance patterns and clinical phenotype. However, definitive diagnosis is made by genetic sequencing of the *RMRP* gene.

TREATMENT AND PROGNOSIS

For patients with severe T-cell defects and infections similar to what are seen with a severe combined immunodeficiency, hematopoietic stem cell transplantation (Chapter 163) is required. Aside from the cellular defect, treatment is directed at the other presenting clinical issues. Life expectancy can be normal, but the prognosis is highly variable and depends on the extent of the cellular defect, the therapies required, and the associated clinical complications.

DEFECTS OF IMMUNE GLOBULIN AND ANTIBODY PRODUCTION

EPIDEMIOLOGY AND PATHOBIOLOGY

Defects of immune globulin and antibody production are due to loss of B-cell development, loss of production of one or more of the immunoglobulin (Ig) isotypes, or loss of functional antibody production. As a group, antibody defects are the most prevalent immune defects and are found in patients of all ages. Selective IgA deficiency is most common in White patients, but the incidence varies from 1 : 400 in Finland to 1: 14,000 or fewer in Black Americans or Asians. Common variable immune deficiency has an estimated incidence of 1 in 50,000; IgG subclass or selective antibody defects are also common, but the incidence is unknown.

Whereas the genetic causes have been elucidated for many of the combined forms of immune deficiency, the genes are not yet known for many of the more common B-cell defects (Table 231-4). Antibody defects can be considered in three main forms: B cells are absent, B cells are present but one or more of the immunoglobulin isotypes are not made, or B cells and immunoglobulin levels are normal but the produced immunoglobulins have no function.

CLINICAL MANIFESTATIONS

Lack of B Cells Leading to Agammaglobulinemia

Genetic Defects of the B-Cell Receptor or Signaling Pathways

In the X-linked form of agammaglobulinemia, the affected gene encodes a tyrosine kinase (BTK) that is essential for downstream signaling from the B-cell receptor. Without these signals, B cells do not survive, thereby leading to profound hypogammaglobulinemia. The incidence of this disease is approximately 1 in 100,000. Although X-linked inheritance is a central feature, the family history may or may not be positive because of de novo mutations.

The main clinical manifestations appear in the first year of life, but males may come to clinical attention later, in some cases not until the second decade. Infections are usually bacterial, generally with encapsulated organisms such as *Streptococcus pneumoniae, Haemophilus influenzae, Staphylococcus aureus,* and *Pseudomonas* species. Affected individuals also have a particular propensity for *Mycoplasma* infections, which may occur in joints or the urinary tract and can be difficult to diagnose.

Other genetic forms of agammaglobulinemia include gene defects of the B-cell receptor itself, such as the μ heavy chain, the surrogate light chain λ5, Igα, and Igβ. Similarly, mutations in signaling proteins immediately downstream from the B-cell receptor lead to the same outcome, with loss of all B cells. Since these genes are not on the X chromosome, these defects, although rare, are found in both sexes.

Good Syndrome

A special case of agammaglobulinemia with loss of B cells in adults is a poorly understood acquired immune defect associated with thymomas (Good syndrome). Although a secondary immune defect, the loss of B cells, with either agammaglobulinemia or hypogammaglobulinemia, leads to many of the same infectious manifestations as with the other profound antibody defects. Quite rare, Good syndrome occurs in adults, most often after age 40 years. Affected individuals are at increased risk of developing opportunistic infections, such as *Pneumocystis jiroveci*, *Candida* infections with nail or other cutaneous involvement, viral infections, autoimmunity, and inflammatory complications such as lichen planus. The connection between thymoma, loss of B-cell function, and the unusual infections remains unclear.

TABLE 231-4 EXAMPLES OF ANTIBODY DEFECTS

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	DISEASE AND COMPLICATIONS
ABSENT B CELLS: SEVERE REDUCTIONS IN IgG, IgA, AND IgM				
X-linked agammaglobulinemia	*BTK*	X-linked	IgG, IgA, and IgM are very low or absent	Severe bacterial infections
Autosomal forms of agammaglobulinemia	Defects of the B-cell receptor or its signaling pathways; λ5, Igα, Igβ; *TCF3*	Autosomal recessive, autosomal dominant	IgG, IgA, and IgM are very low or absent	Severe bacterial infections
Good syndrome	Unknown	Unknown	Few or absent B cells; variable hypogammaglobulinemia	Associated with thymoma; may have opportunistic infections
B CELLS PRESENT: BUT LOW SERUM IgG, IgA, AND/OR IgM				
Common variable immune deficiency	Unknown in 70%	Unknown	Low IgG, IgA, and/or IgM	Bacterial infections, autoimmunity, other inflammatory complications
Defects of B-cell receptors	*CD19, CD81, CD20, CD21, TACI, BAFFr, TWEAK*	Autosomal recessive, autosomal dominant and sporadic	Low IgG, IgA, and/or IgM	Recurrent infections
Defects of signaling, activation and/or regulation (common variable immune deficiency phenotype)	*ICOS, NFKb1, NFKb2; PI3KCD; PI3KR1; CTLA4, IKAROS, LRBA, STAT3*, etc.	Autosomal recessive, autosomal dominant with variable penetrance; sporadic	Variably low IgG, IgA, and/or IgM; antibody defects. Increased IgM in *PI3KCD*	Recurrent infections and autoimmunity; variable clinical expression
B CELLS PRESENT: SEVERE REDUCTION IN SERUM IgG AND IgA BUT NORMAL OR ELEVATED IgM				
X-linked hyper-IgM syndrome	*CD40L*	X-linked	IgG and IgA decreased; IgM may be normal or increased; B-cell numbers may be normal or increased	Bacterial and opportunistic infections, neutropenia, autoimmune disease
CD40 deficiency	*CD40*	Autosomal recessive	Low IgG and IgA; normal or increased IgM	Bacterial and opportunistic infections, neutropenia, autoimmune disease
Defects of DNA recombination	*AID* and *UNG*	Autosomal recessive	IgG and IgA decreased; IgM increased	Bacterial infections; enlarged lymph nodes and germinal centers
B CELLS PRESENT: ISOTYPE DEFICIENCIES				
Selective IgA deficiency	Unknown	Unknown	IgA absent	Usually asymptomatic; allergies and autoimmunity may be more common
IgA with IgG subclass deficiency	Unknown	Unknown	Reduced IgA with decrease in one or more IgG subclass (usually IgG2/4)	Infections in some with loss of antibody
IgG subclass deficiency	Unknown	Unknown	Reduction in one or more IgG subclass	Asymptomatic in many; infections in some with loss of antibody
B CELLS PRESENT: NORMAL IgG, IgA, AND IgM				
Antibody deficiency	Unknown	Unknown	Normal serum immunoglobulins but no vaccine responses to protein and carbohydrate antigens or vaccines	May lead to recurrent infections

BAFF-R = B-cell activating factor receptor; *Btk* = Bruton tyrosine kinase; CTLA4 = cytotoxic T-lymphocyte–associated protein 4; ICOS = inducible T-cell costimulator; Ig = immunoglobulin; LRBA = LPS responsive beige-like anchor protein; *PI3KCD* = phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit delta; STAT3 = signal transducer and activator of transcription 3; TACI = transmembrane activator and CAML interactor; TWEAK = tumor necrosis factor ligand superfamily member 12.

Hypogammaglobulinemia with B Cells Present

Common Variable Immune Deficiency

Patients with common variable immune deficiency have varying degrees of hypogammaglobulinemia ranging from almost total loss of immunoglobulins to more modest reductions of IgG and IgA or IgM. Common variable immune deficiency is relatively common, with a prevalence of 1 : 25,000 to 1 : 50,000. An increasing number of genes leading to loss of B-cell function and the common variable immune deficiency phenotype have been identified in approximately 30% of patients, some of whom have inflammatory or autoimmune complications (see Table 231-4).[17] However, the majority of subjects with hypogammaglobulinemia do not have a known gene defect.

The clinical onset is later than for other immune defects (generally between ages 20 to 40 years), and the clinical presentation is highly heterogenous. Delays in diagnosis are common. Before diagnosis, some subjects with common variable immune deficiency will have had one or more episodes of pneumonia, sometimes leading to empyema. The bacterial species most commonly found include *S. pneumoniae, H. influenzae, S. aureus*, and *Mycoplasma* species. Over time, bronchiectasis (Chapter 78) may develop. Gastrointestinal tract issues are common and may be infectious (e.g., *Giardia, Campylobacter,* norovirus) or inflammatory, including lymphoid hyperplasia and forms of inflammatory bowel disease that lead to malabsorption. However, a biopsy will show loss of plasma cells in the gastrointestinal mucosa. About one quarter of patients with common variable immune deficiency have autoimmune conditions such as thrombocytopenia, hemolytic anemia, achlorhydria, pernicious anemia, and granulomatous disease in lymphoid organs, lungs, brain, or skin, suggesting sarcoidosis. Clinically, lymphadenopathy is common, and splenomegaly is noted in about 30% of cases. Malignant disease is also increased, usually B-cell lymphomas, but other cancers also may appear.

Hyperimmunoglobulin M Syndromes

The hyperimmunoglobulin M (hyper-IgM) syndromes are defects in which the isotype switch is lost. B cells from these patients produce IgM, but they do not secrete IgG or IgA. The prototypic form is the X-linked version in which an essential T-cell activation receptor, which is the CD40 ligand that is encoded on the X chromosome, is missing or nonfunctional. Mutations in the gene for its receptor partner, which is the CD40 ligand on B cells, lead to a similar defect. Several other genetic disorders lead

to a similar immunologic phenotype, including defects of the gene for enzyme activation–induced cytidine deaminase *(AICDA)* and uracil-DNA glycosylase, both important for DNA recombination. Three other gene defects may present with increased serum IgM: *PI3KCD, PI3KR1,* and NEMO *(IKBKG;* see Table 231-7).

The complications of the hyper-IgM syndromes include neutropenia, bacterial infections, *P. jirovecii* pneumonia, autoimmunity, enteropathy similar to common variable immune deficiency, and unusual cancers.[18] In the X-linked hyper-IgM syndrome, a predilection to infection with *Cryptosporidium* can lead to irreversible liver disease.

Selective IgA Deficiency

Selective IgA deficiency (IgA <7 mg/dL with other isotypes normal) is the most common of the primary immunodeficiency disorders, but most affected individuals are asymptomatic. Lack of infections in most subjects is generally ascribed to the overlapping and compensatory role of other immune functions. However, allergies, autoimmunity, increased serum IgE, asthma, rheumatoid arthritis, gluten intolerance, and inflammatory bowel disease are more common in individuals who have selective IgA-deficiency. Presumably owing to the loss of secretory IgA, *Giardia* infections may occur (Chapter 322). Some persons with IgA deficiency also are deficient in IgG2 and IgG4, and the loss of antibacterial antibody leads to severe infections and, in some cases, chronic lung disease.[19]

IgG Subclass Defects

The prevalence of defects in subclasses of IgG is difficult to determine, partly because normal laboratory ranges vary. Despite their structural differences, functional roles of IgG isotypes have considerable overlap, so the importance of isotype defects can be limited, especially if loss of antibody is not demonstrable. The clinical consequences depend on how much antibody function is lost. In adults, IgG3 deficiency appears to be the most common form but is likely of no clinical significance. However, low IgG2 or IgG4, most often found in individuals who have selective IgA deficiency, may lead to a profound deficiency of antibody production, especially to carbohydrate antigens such as contained in the pneumococcal vaccine.

Antibody Deficiency with Normal Immunoglobulins

The loosely described defect termed antibody deficiency with normal serum immunoglobulins, also termed specific antibody deficiency, is complex and heterogenous. All ages are affected, but the incidence is unknown. Although B cells are present, levels of IgG, IgA, and IgM are normal or near normal. Affected individuals do not form protective levels of serum antibodies after having an infectious exposure or vaccination with protein and/or carbohydrate vaccines. In milder cases, the pneumococcal vaccine does not result in sufficient antibody titers for protection. In the most severe cases, even strong immunogens such as herpes zoster or tetanus vaccines are ineffective.

DIAGNOSIS

The diagnosis of antibody defects is based on the laboratory tests of numbers of B cells, serum immunoglobulin levels (IgG, IgA, and IgM), and an evaluation of a panel of vaccine responses to determine the levels of functional antibody. If B cells are absent and the levels of immunoglobulins are very low, further antibody testing is not required. For a young male with a family history of males with immune deficiency, the diagnosis of X-linked agammaglobulinemia or hyper-IgM can be established by flow cytometry (to determine numbers of B cells for X-linked agammaglobulinemia) or by genetic tests (hyper-IgM). For older individuals (generally older than age 45 years), a thymoma may be sought by chest computed tomography, which may show a mass in the mediastinum. Most subjects with hypogammaglobulinemia will have B cells in their peripheral blood and some amount of serum IgG, IgA, or IgM. In these cases, the loss of functional antibody should be tested to determine if protective titers of antibody to common vaccine antigens (i.e., tetanus, diphtheria, *H. influenzae*, and pneumococci) can be detected. In some cases, revaccination may be needed to determine if a response occurs (tested again in 4 to 6 weeks). When high levels of B cells are found in adults, the possibility of a clonal B-cell expansion should be considered (e.g., chronic lymphocytic leukemia). For individuals who have IgG subclass defects or normal immunoglobulins levels, a panel of antibody titers should be obtained to determine immune competence or immune deficits. Genetic counseling is often important, and genetic testing can identify causative genes that may guide therapeutic decisions when autoimmune or inflammatory complications are present.

TREATMENT

The essential treatment of significant IgG antibody defects is intravenous or subcutaneous immune globulin, usually given in doses of 400 to 600 mg/kg body weight per month. Defects that require IgG replacement are conditions in which B cells are absent (X-linked agammaglobulinemia, other agammaglobulinemias, the hyper IgM syndromes, IgG subclass defects with demonstrable loss of antibody function, and some cases of loss of antibody with normal immunoglobulins; Table 231-4). Individuals who have IgA deficiency do not require immune globulin replacement unless they have a clear loss of functional antibody. The intravenous forms are usually given every 3 or 4 weeks, the subcutaneous forms weekly, biweekly, or monthly, depending on product and body weight. Indwelling ports are discouraged.

Most patients also require occasional courses of antibiotics, chosen on the basis of culture results, at intervals dictated by clinical events. Many affected individuals have recurrent pneumonias and resulting abnormal lung functions. In such patients, prophylactic antibiotics (e.g., azithromycin 250 mg three times a week) may reduce the rate of respiratory infections.[A1]

If patients develop autoimmune or inflammatory complications, treatments are as for immunocompetent persons but with a view to minimizing courses of immune suppression. Immune cytopenias may be treated with rituximab under expert supervision, but splenectomy should be avoided. For granulomatous lung infiltrations, rituximab plus azathioprine or mycophenolate mofetil can be useful.[20] Chronic interstitial lung disease, lymphoid hyperplasia, and gastrointestinal enteropathy may be difficult to treat, but treatments for Crohn disease (Chapter 127) may be successful.

PROGNOSIS

The prognosis for individuals with antibody defects is variable and depends on the degree of the defect, the response to treatment, whether organ damage has occurred, and whether other complications have developed. If patients who have a pure B-cell defect are diagnosed and treated early with sufficient immune globulin, the prognosis appears to be excellent. Individuals who have selective IgA deficiency can have a clinical course and life expectancy that are indistinguishable from age-matched healthy peers.

Patients with common variable immune deficiency have a prognosis that relates to their varying degrees of hypogammaglobulinemia, which range from almost total loss of immunoglobulins to more modest reductions of IgG and IgA or IgM. However, even patients with more modest reductions often have additional complications, in some cases because the diagnosis has been delayed until pulmonary or other damage has occurred. For individuals who have defects of IgG subclasses or antibody deficiencies and who are treated as required with immune globulin reconstitution, neither increased morbidity nor mortality is expected.

COMPLEMENT DISORDERS

The complement system (Chapter 37) is a network of proteins that both amplify and control many actions of the immune system. The three main branches of the complement system are the classical, alternative, and lectin pathways; deficiencies of individual components lead to increased susceptibility to infections, autoimmunity, and inflammatory diseases (Table 231-5).

EPIDEMIOLOGY

Complement C2 deficiency is found in 1 : 10,000 White individuals, who usually have a conserved major histocompatibility complex haplotype due to a founder defect. More than 95% of C2-deficient individuals are homozygous for the same C2 mutation. The other complement component defects are rare but found in unequal distribution in selected populations: C6 deficiency is more common in persons of African descent and C9 deficiency in Asians, with an estimated incidence of 0.036 to 0.095%.

PATHOBIOLOGY

The classical pathway is triggered by interaction of the Fc portion of an IgG1, IgG2, IgG3, or IgM antibody with C1q, which subsequently engages C1r, C1s, C2, and C3, thereby leading to activation of C4, C5, C6, C7, C8, and C9, resulting in lysis of bacteria (Chapter 37). The alternative pathway is activated in an antibody-independent manner and involves opsonization of bacteria with subsequent involvement of C3 and the alternative pathway. The lectin pathway includes other serum binding proteins that coat bacteria or fungi, thereby leading to downstream activation of complement and the assembly

TABLE 231-5 EXAMPLES OF COMPLEMENT DEFECTS

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTIONS	DISEASE AND COMPLICATIONS
C1q, C1r, C1s deficiency	*C1qA, C1qB, C1qC; C1r, C1s*	Autosomal recessive	Absent CH_{50} hemolytic activity	Loss of early complement activation, impaired dissolution of immune complexes, impaired clearance of apoptotic cells	Bacterial infections, SLE-like syndrome, rheumatoid disease, multiple autoimmune diseases, infections
C4 deficiency	*C4A* and *C4B*	Autosomal recessive	Absent CH_{50} hemolytic activity	Loss of early complement activation	Bacterial infections
C2 deficiency	*C2*	Autosomal recessive	Absent CH_{50} hemolytic activity	Loss of early complement activation	Bacterial infections, SLE-like syndrome, vasculitis, early atherosclerosis, polymyositis, glomerulonephritis
C3 deficiency	*C3*	Autosomal recessive	Absent CH_{50} hemolytic activity	Loss of classical and alternative pathways of complement activation	Life-threatening pyogenic infections, SLE-like disease, glomerulonephritis, atypical hemolytic-uremic syndrome
C5, C6, C7, C8 deficiency	*C5*	Autosomal recessive	Absent CH_{50} hemolytic activity	Loss of complement activation	Neisserial infections, SLE
C9 deficiency	*C9*	Autosomal recessive	Reduced CH_{50} and AH_{50} hemolytic activity	Partial loss of complement activation	Some *Neisseria* infections
C1 inhibitor deficiency	*C1* inhibitor	Autosomal dominant	Activation of complement; low levels of C4 and C2	Loss of regulation of activities of complement C1	Angioedema

AH_{50} = alternative hemolytic complement; CH_{50} = total hemolytic complement; SLE = systemic lupus erythematosus.

of the membrane attack complex, which are the C7, C8, C9 components that are responsible for microbial lysis. The genes of the complement system are located on many chromosomes, and in general the defects are autosomal recessive, with the exception of defects of X-linked properdin.

More complex but equally potent is the role that the complement proteins play in immune regulation. Complement is important for clearing immune complexes and possibly apoptotic cells. In addition to the three pathways of activation, the complement system includes an even larger number of control proteins that, when genetically defective, also lead to severe infections, hemolytic-uremic syndrome, severe eclampsia, glomerulonephritis, thrombosis, and macular degeneration.

CLINICAL MANIFESTATIONS

Since opsonization of bacteria is essential for the function of antibodies, patients with these defects can have infections similar to what are seen in patients with immunoglobulin deficiencies. Loss of these classical components may lead to severe clinical consequences, but individuals who are deficient in C2 in particular but also in C4 and C5-C9 may have no history of illness. Severe bacterial infections are common, especially in individuals who have defects of C3, which lies at the convergence of the three pathways. With loss of C6,[21] C7, C8, C9, or properdin, *Neisseria gonorrhoeae* (Chapter 275) or *Neisseria meningitidis* (Chapter 274) is more common. With loss of the early components of the classical system, C1q, C1r, C1s, C2, and C4, autoimmunity, especially systemic lupus erythematosus (Chapter 245), is common[22] and occurs in more than 90% of patients who have defects of C1q and 75% of patients who have defects of C4.

DIAGNOSIS

Deficiencies of complement are diagnosed by testing total serum hemolytic complement (CH_{50}) and the alternative hemolytic complement (AP_{50}). Further testing usually includes measurement and function of individual serum complement proteins to determine the most applicable diagnosis. False-positive results can occur if the blood sample is mishandled, so abnormal tests often are repeated to confirm the diagnosis.

TREATMENT

No specific treatments are available for complement deficiencies. Prompt antibiotic therapy is indicated for acute infections, and autoimmune diseases require their usual treatments. Periodic immunizations with pneumococcal, *H. influenzae*, and meningococcal vaccines may be helpful to boost antibody titers to enhance bacterial clearance.

PROGNOSIS

The prognosis of complement defects is highly variable, and most of these defects have been found in otherwise healthy persons. The prognosis for patients who develop infections or autoimmune complications depends on the severity of the manifestations and their response to treatment. Although C2 deficiency is commonly viewed as being asymptomatic, some data suggest a higher incidence of premature arteriosclerotic cardiovascular disease.

C1 INHIBITOR DEFICIENCY

A diagnosis of C1 INH deficiency is suggested by a history of recurrent attacks of angioedema or in some cases (25%) episodes of recurrent abdominal pain due to edema (Chapter 232).

PHAGOCYTIC DEFECTS

EPIDEMIOLOGY AND PATHOBIOLOGY

Abnormalities of the phagocytic system are categorized as neutropenia, abnormal neutrophil morphology, defective cell adhesion and migration, or defective microbial killing (Chapters 153 and 155) (E-Table 231-3). Genetic defects impairing neutrophil development, adhesion, locomotion, or intracellular killing are rare. The most common genetic abnormality is chronic granulomatous disease, which has an estimated incidence of 1 : 100,000 to 1 : 200,000.

Circulating neutrophils are attracted to sites of inflammation by complement components C5a, chemokines, and bacterial byproducts, but traveling to these sites requires migration through capillaries and into tissues. The best-known diseases in which neutrophil adhesion is impaired are the leukocyte adhesion defects types 1, 2, and 3. Other defects of neutrophil motility include juvenile periodontitis, Shwachman-Diamond syndrome, and Chédiak-Higashi syndrome.

About two-thirds of patients with chronic granulomatous disease are males who have defects in an X-linked gene encoding $gp91^{phox}$. Autosomal defects in $p47^{phox}$ occur in 20% of patients and are the next most common form. Other autosomal forms due to defects in the gene encoding the $p22^{phox}$ or $p67^{phox}$ subunits each account for about 5% of cases.

CLINICAL MANIFESTATIONS

The genetic neutrophil disorders have specific clinical associations: delayed separation of the umbilical cord and poor wound healing in leukocyte adhesion defect-1; growth delay and Bombay blood group in leukocyte adhesion defect-2; peripheral nerve conduction defects, pigmentary dilution with partial oculocutaneous albinism, easy bruising, and risk of hemophagocytic disease in Chédiak-Higashi syndrome; and pancreatic insufficiency (fat malabsorption), growth failure, and skeletal abnormalities in Shwachman-Diamond syndrome (Chapter 151). For both Shwachman-Diamond syndrome and the severe congenital neutropenias (Chapter 153), patients are at risk of developing myelodysplastic disease and leukemia.

The clinical manifestations of chronic granulomatous disease[23] usually include bacterial or fungal infections. Males with the X-linked form will generally present in the first decade of life, whereas patients who have autosomal

E-TABLE 231-3 EXAMPLES OF PHAGOCYTE DEFECTS

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTIONS	DISEASE AND COMPLICATIONS
DEFECTS OF NEUTROPHIL DIFFERENTIATION					
Severe congenital neutropenia	*ELANE, GFI1, HAX1; G6PC3; VPS45; G6PT1; WAS; LAMTOR2; TAZ; COH1 USB1; JAGN1; CLPB; CSF3R; SMARCD2*	Autosomal dominant, X-linked, or autosomal recessive	Neutropenia	Impaired myeloid differentiation	Susceptible to infections, myelodysplasia, syndromic features in some
Cyclic neutropenia	*ELANE*	Autosomal recessive	Neutropenia at 21-day intervals	Impaired and cyclic myeloid differentiation	Susceptible to infections at intervals, periodontitis
DEFECTS OF MOTILITY					
Leukocyte adhesion deficiency (types 1-3)	*ITGB2, SLC35C1; FERMT3*	Autosomal recessive	Leukocytosis	Impaired neutrophil adherence and chemotaxis	Delayed cord separation for type 1, skin ulcers, poor wound healing, periodontitis
Rac 2 deficiency	*RAC2*	Autosomal dominant	Leukocytosis	Impaired adherence, chemotaxis, O_2 production	Poor wound healing
Shwachman-Diamond syndrome	*SBDS*	Autosomal recessive	Pancytopenia	Impaired chemotaxis	Exocrine pancreatic insufficiency, chondrodysplasia, risk of leukemia
Chédiak-Higashi syndrome	*LYST*	Autosomal recessive	Neutrophils with giant inclusions; hair: pigment clumps	Impaired chemotaxis	Partial albinism, recurrent infections, late-onset primary encephalopathy, increased lymphoma risk
DEFECTS OF RESPIRATORY BURST					
Chronic granulomatous disease	*gp97phox (CYBB) p47phox (NCF1) p22phox (CYBA) p67phox (NCF2) p40phox (NCF4)*	X-linked or autosomal recessive	Normal or increased neutrophil counts but loss of respiratory burst	Impaired bacterial killing	Susceptible to bacterial and fungal infections

ACTB = actin beta; *CD18* = encodes an integrin beta chain; *CLPB* = ClpB homolog; *COH1* = Cohen syndrome; *CSF3R* = colony-stimulating factor 3 receptor; *CTSC* = cathepsin C; *CYBA* = cytochrome B-245 alpha chain; *CYBB* = cytochrome B-245 beta chain; *ELANE* = elastase; *FERMT3* = Fermitin family homolog 3; *FPR1* = formyl receptor peptide 1; *G6PC* = glucose-6-phosphatase catalytic subunit 3; *G6PT1* = glucose-6-phosphate transport; *GFI1* = growth factor independent 1 transcriptional repressor; *HAX1* = HCLS1 associated protein X-1; *ITGB2* = integrin subunit beta 2; *JAGN1* = jagunal homolog 1; *LAMTOR2* = late endosomal/lysosomal adaptor; *LYST* = lysosomal trafficking regulator; *NCF1* = neutrophil cytosolic factor 1; *NCF4* = neutrophil cytosolic factor 4; *RAC2* = Ras-related C3; *SBDS* = Schwachman-Bodian-Diamond syndrome; *SLC35C1* = solute carrier family 35; *SMARCD2* = SWI/SNF related matrix associated; *TAZ* = tafazzin; *USB1* = U6 SnRNA biogenesis phosphodiesterase 1; *VPS45* = vacuolar protein sorting 45 homolog; *WAS* = Wiskott-Aldrich syndrome; *WDR1* = WD repeat domain 1.

forms may present in their second decade of life. Regardless of the genetic cause, most patients with chronic granulomatous disease have one or more episodes of pneumonia; the most common causes of infection are *Staphylococcus, Burkholderia cepacia, Klebsiella, Aspergillus, Serratia*, and *Nocardia* species. Common clinical manifestations include acute or chronic lymphadenitis, colitis that leads to recurrent diarrhea, *Staphylococcus* liver abscess, osteomyelitis, and rectal abscess. Exposure to contaminated water or decaying plant material (compost, mulch) presents significant risk to patients who have chronic granulomatous disease because they are also prone to infections with unusual organisms, such as *Chromobacterium violaceum, Trichosporon inkin, Francisella philomiragia*, and *Granulibacter bethesdensis*.

TREATMENT

The diagnosis and management of patients with neutropenia is discussed in Chapter 153.

IMMUNE DYSREGULATION SYNDROMES

Immune dysregulation syndromes are mostly monogenic diseases and have in common lymphoid proliferation, immune activation, and inflammatory or autoimmune complications. These diseases include the hemophagocytic lymphohistiocytosis diseases (Chapter 155), the lymphoproliferative syndromes linked to Epstein-Barr virus infection, autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy, autoimmune lymphoproliferative syndrome, defects of T-regulatory cells, and immune defects that lead to severe early-onset inflammatory bowel disease (Table 231-6).

EPIDEMIOLOGY

The estimated incidence of the genetic hemophagocytic lymphohistiocytosis syndromes is 1 : 50,000, the incidence of X-linked lymphoproliferative disease is 1 to 3 in 1,000,000, and the incidence of autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy is high in Finland (1 in 25,000) and in Sardinians and Iranian Jews (1 in 9000) but otherwise much rarer. The incidence of autoimmune lymphoproliferative syndrome and defects of T-regulatory cells is unknown.

PATHOBIOLOGY

Hemophagocytic lymphohistiocytosis[24] is a genetic or secondary form of extreme and potentially life-threatening immune activation (Chapter 155). The familial form is a heterogeneous autosomal recessive disorder due to mutations in one of five genes essential for control of T-cell cytotoxicity. Immune activation leads to expansion of poorly controlled cytotoxic T cells and macrophages, thereby leading to the release of interferon-γ (IFN-γ), IL-1, IL-6, and IL-10. Patients have high fevers, cytopenias, liver dysfunction, coagulopathy, and sometimes neurologic symptoms.

Monogenic defects that lead to impaired immunity to Epstein-Barr virus produce another group of immune dysregulation syndromes.[25] The most common form is the X-linked proliferative disorder (XLP) that is caused by mutations of the X-linked *SH2D1A* gene. Other genetic causes for loss

TABLE 231-6 EXAMPLES OF DISEASES OF IMMUNE DYSREGULATION

TYPE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTION	DISEASE AND COMPLICATIONS
Familial hemophagocytic lymphohistiocytosis syndromes	*PRF1, UNC13D, STX11, STXBP2, FAAP24 SLC7A7*	Autosomal recessive, autosomal dominant	Anemia, neutropenia, thrombocytopenia, abnormal liver functions, high ferritin and serum IL-2 receptor, hemophagocytosis in bone marrow and liver	Decreased to absent NK cells and cytotoxic activities	Fever, hepatosplenomegaly, cytopenias, hemophagocytic lymphohistiocytosis, neurologic disease in some
Chédiak-Higashi syndrome	*LYST*	Autosomal recessive	Neutrophils with giant inclusions; hair: pigment clumps	Impaired chemotaxis	Partial albinism, recurrent infections, late-onset primary encephalopathy, increased lymphoma risk
Lymphoproliferative syndromes (susceptibility to EBV)	*SH2D1A, XIAP, ITK, CD27, CTPS1, CD70, RASGRP1, MAGT1*	X-linked, autosomal recessive	Epstein-Barr virus infection; decreased NK cells and CD8+ CTL activation; deficient NK-T cells; anemia; hypogammaglobulinemia in some	Loss of function of NK-T cells leading to impaired viral control	Clinical and immunologic features triggered by Epstein-Barr virus infection; lymphoproliferation, lymphoma
Autoimmune polyendocrinopathy–candidiasis ectodermal dystrophy (APECED)	*AIRE*	Autosomal recessive	Endocrine dysfunction; hepatitis	Loss of thymic self-tolerance	Autoimmunity leading to hypoparathyroidism, hypothyroidism, diabetes, and adrenal and gonadal dysfunction; cutaneous candidiasis; hepatitis
Autoimmune lymphoproliferative syndrome (ALPS)	*FAS, FAS ligand; caspase 10; caspase 8; KRAS; NRAS*	Autosomal dominant	Increased double-negative T cells (CD4−/CD8−), increased serum B_{12}	Defects in lymphocyte apoptosis	Splenomegaly, lymphadenopathy, autoimmune cytopenias; increased risk of lymphoma
Genetic defects of T-regulatory cells	*FOXP3, CD25, CTLA4, IL2RA, IL2RB, LRBA, STAT3 (GOF), BACH2, DEF6, STAT5B* and *STAT1; STAT5b*	X-linked, autosomal recessive, autosomal dominant	Autoimmunity, diabetes, anemia, eosinophilia, high serum IgE in some	Lack of (or impaired function of) CD4+, CD25+, FOXP3+ regulatory T cells (Tregs)	Enteropathy, hepatosplenomegaly, dermatitis, eczema, early-onset diabetes, thyroiditis, hemolytic anemia, thrombocytopenia, elevated IgE and IgA; recurrent infections
Immune dysregulation leading to colitis	*IL-10, IL-10Ra, IL-10Rb, NFAT5, TGFB1, RIPK1*	Autosomal recessive, autosomal dominant	Normal lymphocyte panels	Defects of immune responses to resident microbes	Severe IBD, recurrent sinopulmonary infections

AIRE = autoimmune regulator; *BACH2* = BTB domain and CNC homolog 2; CTL = cytotoxic T lymphocyte; *CTLA4* = cytotoxic T-lymphocyte-associated protein 4; *CTPS1* = CTP synthase 1; *DEF6* = DEF6 guanine nucleotide exchange factor; EBV = Epstein-Barr virus; *FAAP24* = Fanconi anemia core complex associated protein 24; *FAS* = Fas cell surface death receptor; *FOXP3* = Forkhead box P3; IBD = inflammatory bowel disease; Ig = immunoglobulin; IL = interleukin; *IL2RA* = IL-2 receptor subunit alpha; *IL2RB* = IL-2 receptor subunit beta; *ITK* = IL-2 inducible T-cell kinase; *KRAS* = KRAS proto-oncogene; *LRBA* = LPS responsive beige-like anchor protein; *LYST* = lysosomal trafficking regulator; *MAGT1* = magnesium transporter 1; *NFAT5* = nuclear factor of activated T cells 5; NK = natural killer; *NRAS* = NRAS proto-oncogene; *PRF1* = perforin; *RASGRP1* = RAS guanyl releasing protein 1; *RIPK1* = receptor interacting serine/threonine kinase 1; *SAP* = SLAM-associated protein; *SH2D1A* = SH2 domain containing 1A; *SLC7A7* = solute carrier family 7 member 7; *STAT1* = signal transducer and activator of transcription 1; *STAT3 (gain of function)* = signal transducer and activator of transcription 3; *STAT5B* = signal transducer and activator of transcription 5B; *STX11* = syntaxin 11; *STXBP2* = syntaxin binding protein 2; *TGFB1* = transforming growth factor beta 1; *UNC13D* = Unc-13 homolog D; *XIAP* = X-linked inhibitor of apoptosis.

of control of Epstein-Barr virus are due to mutations in *XIAP* (20 to 30%) or, rarely, *ITK CD27, MAGT1,* or *CD70*. *XLP, XIAP,* and *MAGT1* are on the X chromosome; the other defects are inherited as autosomal recessive traits. In each case, infection with Epstein-Barr virus leads to an acute illness with lymphoproliferation, progressive but variable hypogammaglobulinemia, and lymphoma in *XLP, ITP,* and *CD27* defects. A unifying theme of these syndromes is loss of function of NK-T cells, a subset of T cells important in viral immunity.

A unique member of the genetic immune dysregulation diseases is autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy or autoimmune polyglandular syndrome type 1 (Chapter 212). The disease is caused by loss of thymic recognition of self-antigens due to mutations in the autoimmune regulator gene *(AIRE)*. Chronic mucocutaneous candidiasis (Chapter 310) may be related to circulating anticytokine antibodies (interferon and IL-17). The transcription factor encoded by the *AIRE* gene, which is found in thymic epithelial cells, is involved in the early negative selection of cells with autoimmune potential.

Defects in lymphocyte apoptosis lead to another form of immune dysregulation; in these subjects, because of impaired death of lymphocytes, lymph nodes and spleen enlarge, and various forms of autoimmunity, especially autoimmune thrombocytopenia and hemolytic anemia, occur. Together, these diseases are commonly referred to as autoimmune lymphoproliferative syndrome. The most common of these defects are due to autosomal dominant mutations in the *FAS* gene, which encodes the important FAS death receptor, and less commonly in the FAS ligand.[26] Both conditions are dominant but have variable penetrance. Much less common forms of autoimmune lymphoproliferation are due to mutations in caspase 8 or 10 or even more rarely the oncogenes *KRAS* and *NRAS* or protein kinase Cδ. In addition, mutations in somatic genes may mimic the clinical presentation of the congenital forms.

Defects of T-regulatory cells are another set of genetic defects that lead to loss of regulation. The defect is generally due to mutations of the X chromosome forkhead box protein 3 *(FOXP3)* gene, which is essential for the development of regulatory T cells. However, other genetic defects may lead to a similar clinical syndrome.

CLINICAL MANIFESTATIONS

Life-threatening accelerated immune activation syndromes are characteristic of hemophagocytic lymphohistiocytosis and other genetic defects that impair cytotoxicity, such as the Chédiak-Higashi syndrome. For autoimmune polyglandular syndrome type 1 (Chapter 212), the usual presentation is cutaneous candidiasis or endocrine insufficiency (i.e., hypoparathyroidism, Addison disease, hypogonadism, and secondary amenorrhea). Chronic diarrhea with malabsorption is also common. Other autoimmune complications may include hepatitis, alopecia, vitiligo, diabetes mellitus, anemia, and pernicious anemia. The immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome, which is a generally lethal disease in males, is characterized by early-onset insulin-dependent diabetes mellitus, enteropathy with severe diarrhea, and eczema-like dermatitis.[27] Other manifestations include anemia, thrombocytopenia, and neutropenia, as well as liver or kidney autoimmune disease.

DIAGNOSIS

The diagnosis of these syndromes may be suspected from the clinical manifestations, family history, and laboratory grounds, but genetic validation is required for definitive diagnosis.

TREATMENT

For the hemophagocytic lymphohistiocytosis diseases and related syndromes, prompt immune suppression by established protocols and intense supportive care are necessary (see Chapter 155).[28] For the genetic forms, hematopoietic stem cell transplantation (Chapter 163) is often required. The lymphoproliferative syndromes associated with Epstein-Barr virus are similar in that prompt supportive care is required and transplantation is potentially curative. Rituximab has been used in these defects to reduce B-cell numbers and the burden of Epstein-Barr virus if infection occurs. Treatment of the cytopenias in the autoimmune lymphoproliferative syndrome includes corticosteroids, rapamycin, mycophenylate, and other agents. For unclear reasons, rituximab may lead to permanent hypogammaglobulinemia in autoimmune lymphoproliferative syndrome, and splenectomy is to be avoided. Patients with autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy usually require endocrine and possibly nutritional management as well as treatment for cutaneous candidiasis. For the defects of T-regulatory cells due to mutations in the immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome, hematopoietic stem cell transplantation is the only curative measure.

PROGNOSIS

The diseases of immune dysregulation have a varied prognosis. For the genetic hemophagocytic lymphohistiocytosis syndromes, Epstein-Barr virus–related lymphoproliferative diseases, and the immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome, immune reconstitution is required. Because of the broad spectrum of manifestations for the autoimmune lymphoproliferative syndrome and for autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy, management of the clinical issues may be sufficient.

DISEASES OF INTRINSIC AND INATE IMMUNITY

As compared with the adaptive immune system, in which a previous exposure is required to form immune memory (Chapter 35), many components of the immune system function quickly without prior exposure. These components of the innate immune system (Chapter 35) include complement, phagocytic cells, and natural killer cells. Screening of large populations for selected microbial diseases has revealed a number of defects of innate immunity (Table 231-7).

EPIDEMIOLOGY AND PATHOBIOLOGY

Innate immunity defects that cause specific infections appear to be rare, and their incidence is not known. Anhidrotic ectodermal dysplasia with immunodeficiency, which is caused by mutations in the *IKBKG* gene that encodes nuclear factor-κB (NF-κB) essential modulator (NEMO), is an X-linked disease. Genetic defects can also occur in toll-like receptors and their signaling pathways (e.g., autosomal recessive defects in *IRAK4* and *MyD88*).

Genetic disorders that lead to chronic mucocutaneous candidiasis may be autosomal dominant or recessive. Patients of any age may have defects in these pathways. The pathogenesis of some of these include genes that disrupt the dectin-1 pathway. Dectin-1 is a surface lectin receptor that recognizes the β1-3 glucan of fungi; downstream mutations in *CARD9* impair the secretion of IL-17A, IL-17F, and IL-22, cytokines that are essential in fungal clearance.

A separate and unique category of innate defects are the cytokine/receptor mutations that impair the functions of cytokines IL-12, IL-23, and IFN-γ, which are required to control mycobacterial and other intracellular infections, such as salmonella. Chronic mycobacterial infections may also occur in patients with autosomal recessive mutations in the gene for signal transducer and activator of transcription 1 *(STAT1),* a gene downstream of both IFN-γ and IFN-α receptors. Defects in toll-like receptors and their signaling pathways are autosomal recessive or X-linked disorders, whereas defects in *GATA2* are inherited in an autosomal dominant fashion.

CLINICAL MANIFESTATIONS

For anhidrotic ectodermal dysplasia with immunodeficiency, the clinical phenotype can include severe bacterial infections and mycobacterial disease as well as ectodermal dysplasia: sparse hair, abnormal tooth development, and lack of sweat glands. Defects in toll-like receptors lead to severe pneumococcal and staphylococcal infections. In contrast, defects of the TL3 pathway lead to early herpes simplex encephalitis. The genetic defects that lead to chronic mucocutaneous candidiasis are heterogenous, and clinical manifestations may range from onychomycosis to invasive fungal infections.

Patients who have cytokine or cytokine receptor defects may have severe viral or fungal infections. Dominant (activating) mutations in *STAT1* may lead to simple cutaneous candidiasis in some patients or to cutaneous candidiasis plus more complex clinical outcomes in other patients. More complex is the syndrome of GATA2 deficiency in which mycobacterial disease may also develop,[29] but other organisms (papillomaviruses, fungi) and serious complications (cytopenias, myelodysplasia, pulmonary

TABLE 231-7 EXAMPLES OF DISEASES OF INNATE IMMUNITY

DISEASE	GENES	INHERITANCE	LABORATORY FEATURES	ALTERED FUNCTION	ASSOCIATED FEATURES
Anhidrotic ectodermal dysplasia with immunodeficiency	*IKBKG*, (NEMO), *IKBA*	X-linked, autosomal dominant	Variable hypogammaglobulinemia with increased IgM in some; lack of antibody response to polysaccharides	Defective NF-κB signaling pathway	Bacterial and mycobacterial infections, ectodermal dysplasia, hair loss, heat intolerance due to loss of sweat glands, tooth abnormalities
IRAK4, MYD88	*IRAK4, MYD88, IRAK1, TIRAP*	Autosomal recessive, X-linked	cytokine responses to toll receptor activators	Defective TIR-IRAK signaling pathway	Bacterial infections, especially *Staphylococcus* and *S. pneumoniae*
Susceptibility to mycobacterial disease	*IL12, IL23R, IFNGR1, IFNGR2* *STAT1, CYBB, TYK2, ISG15, SPPL2A, JAK1, RORC*	Autosomal recessive, autosomal dominant, X-linked	Cultures positive; impaired IFN-γ/IL-23 production or responses.	IFN-γ signaling; IFNγ production defect; Impaired cellular development	Susceptibility to mycobacteria and *Salmonella*
Herpes simplex encephalitis	*TLR3* *UNC93B1* *TRAF3, TICAM1, TBK1, IRF3, DBR1*	Autosomal dominant, autosomal recessive	Impaired cytokine responses to TLR3 activators	Defective IFN-α, IFN-β, and IFN-γ induction	Herpes simplex virus 1 encephalitis
Predisposition to fungal diseases	*CARD9*	Autosomal recessive	Fungal cultures positive	Defective CARD9 signaling pathway	Invasive candidiasis and other fungal diseases
Chronic mucocutaneous candidiasis	*IL17RA, IL17C* *IL17F* *STAT1* *AIRE* *TRAF3IP2*	Autosomal recessive, autosomal dominant	Fungal cultures positive	Defective IL-17R signaling pathways	Mucocutaneous candidiasis
IL-12, IL-23 receptor deficiency	*IL12RB* *IL12* *IL23*	Autosomal recessive	Mycobacterial cultures positive	Defective cytokine receptor binding and signaling	Mycobacterial and salmonella infections
IFN-γ receptors 1 and 2 deficiency	*IFNGR1* *IFNGR2*	Autosomal recessive	Mycobacterial cultures positive	Defective IFN-γ binding and signaling	Mycobacterial and salmonella infections
GATA2 deficiency	*GATA2*	Autosomal recessive, autosomal dominant	Multilineage cytopenias; very low monocyte numbers		Infections with mycobacteria, papillomaviruses, histoplasmosis, alveolar proteinosis but also myelodysplasia and leukemias

AIRE = autoimmune regulator; *CYBB* = cytochrome B-245 beta chain; *DBR1* = debranching RNA lariats 1; *GATA2* = a member of the GATA family of zinc-finger transcription factors; IFN = interferon; *IFNGR1* = ligand-binding chain (alpha) of the gamma interferon receptor; *IFNGR2* = ligand-binding chain (beta) of the gamma interferon receptor; *IKBA* = NF-kappa-B inhibitor alpha; IL = interleukin; *IL12* = interleukin-12; *IL12RB* = interleukin-12 receptor B; *IL17* = interleukin-17; *IL17C* = interleukin-17C; IL-17R = interleukin-17 receptor; *IL17RA* = interleukin-17 receptor A; *IL23R* = interleukin-23 receptor; *IRAK1* = interleukin-1 receptor–associated kinase 1; *IRAK4* = interleukin-1 receptor–associated kinase 4; *IRF3* = interferon-regulatory factor 3; *ISG15* = ISG15 ubiquitin-like modifier; *JAK1* = Janus kinase-1; *MYD88* = myeloid differentiation primary response protein; *NEMO (IKBKG)* = NF-kappa-B essential modulator; NF-κB = nuclear-factor-κB; *RORC* = RAR-related orphan receptor C; *SPPL2A* = signal peptide peptidase-like 2A; *STAT1* = signal transducer and activator of transcription 1; *TBK1* = TANK binding kinase 1; TIR = intracytoplasmic toll and IL-1-receptor; *TIRAP* = TIR domain–containing adaptor protein; TLR = toll-like receptor; *TLR3* = toll-like receptor 3; *TRAF3* = TNF-receptor–associated factor 3; *TRAF3IP2* = TRAF3 interacting protein 2; *TRIF (TICAM1)* = TIR domain–containing adapter-inducing interferon-β; *TYK2* = tyrosine kinase 2; *UNC93B1* = Unc-93 homolog B1.

alveolar proteinosis, peripheral edema) may be foremost, and members of the same family with the same mutations may have very different clinical manifestations.

DIAGNOSIS

The diagnosis of innate defects is first based on exclusion of other causes and then confirmed by genetic testing. The family history may be helpful, but the extreme range of clinical phenotypes may obscure easy recognition of patients who have mutations in *STAT1* or *GATA2*.

TREATMENT AND PROGNOSIS

The treatment of innate defects includes antimicrobial therapy to clear active infections and often relevant prophylactic therapy under expert supervision on an ongoing basis. For the more severe defects, hematopoietic stem cell transplantation (Chapter 163) is required.

AUTOINFLAMMATORY DISORDERS

Inherited autoinflammatory syndromes are described in Chapter 240.

BONE MARROW FAILURE DEFECTS

Bone marrow failure syndromes are discussed in Chapter 151.

232 URTICARIA AND ANGIOEDEMA

SARBJIT S. SAINI

DEFINITION

Acute and chronic urticaria, which involve the dermis, are caused by the excessive release of histamine from mast cells—sometimes acute and sometimes chronic, and sometimes with and sometimes without a trigger. Angioedema, which also involves subcutaneous tissue, can accompany histamine-driven urticaria or can be caused by excessive bradykinin, either as a result of hereditary angioedema or specific provoking agents.

HISTAMINE-INDUCED ACUTE AND CHRONIC URTICARIA

Episodes of urticaria or angioedema are classified by their duration and by the presence of a known trigger. Acute urticaria persists for less than 6 weeks, whereas chronic urticaria is defined by recurrent urticaria, angioedema, or both for more than 6 weeks.[1] Chronic urticaria is further divided into the 20% or so of patients who have a specific physical stimulus or trigger (e.g., heat, cold temperature, elevation in body temperature, vibration, or sunlight) for their hives (chronic inducible urticaria)[2] as compared with the 80% or so who experience skin lesions of chronic spontaneous urticaria without a clear trigger. The most common presentation of chronic spontaneous urticaria is urticaria alone (50%), followed by both urticaria and angioedema (40%) and recurrent angioedema only (10%). The term chronic spontaneous urticaria encompasses clinical phenotypes that include both urticaria and angioedema.

EPIDEMIOLOGY

About 25% of both females and males will have an episode of acute urticaria in their lifetime.[3] For chronic urticaria, the estimated prevalence is 0.1 to 1%, with an average onset in third to fifth decade of life,[4] and adult females are more often affected than males (2:1). In the majority of patients, the duration of chronic urticaria is self-limited and ranges from 2 to 5 years.[5] In individuals with chronic inducible urticarias, however, the duration can be much longer.

PATHOBIOLOGY

A central feature of skin lesions of urticaria is the activation of mast cells, which are found throughout the skin of the body in varying numbers. Within minutes, activated mast cells can release mediators such as stored histamine, leukotriene C4, and prostaglandin D2, thereby leading to vasodilation, leakage of plasma into the dermis, and creation of the sensation of pruritus via activation of sensory nerves.[6] A few hours later, mast cells release cytokines that can lead to the recruitment of lymphocytes, eosinophils, and basophils into the skin tissue. Angioedema, which results from a similar extravasation of fluid in deeper dermal and subcutaneous tissues, takes 24 to 72 hours to resolve.

Acute Urticaria

In acute urticaria, the activating triggers for mast cells include immediate hypersensitivity reactions to drugs or foods, as well as to the inflammatory process of a viral illness. However, no clear trigger is found in over 50% of cases.[7] Among the implicated foods in children are milk, egg, and peanuts, whereas peanuts, tree nuts, fish, and shellfish predominate in adults. These food allergens and some drugs (e.g., penicillins) crosslink specific IgE that is bound to the surface of mast cells via high-affinity receptors (FcεRI) and activate the release of mediators. Commonly implicated drugs are antibiotics (penicillins, sulfonamides), nonsteroidal anti-inflammatory drugs, and muscle relaxants. Mast cells can be activated by non–IgE-based pathways via a receptor called MRGPRX2. Drugs that can activate this receptor include opioids, muscle relaxants, and antibiotics such as ciprofloxacin.[8] Hives also can be precipitated by scombroid food poisoning (Chapter 98), in which fish that are contaminated with bacteria produce histamine, which then leads to hives.[9]

Chronic Urticaria

In chronic spontaneous urticaria, the mechanisms by which mast cells are activated are less clear. Serum autoantibodies are detected in up to 40% of cases, thereby suggesting an autoimmune mechanism. Such autoantibodies include IgG that targets either the high-affinity IgE receptor (FcεRI) or IgE and thereby activates skin mast cells. Some patients with chronic spontaneous urticaria express thyroid IgG autoantibodies.[10]

FIGURE 232-1. Dermographism.

In chronic inducible urticaria, the trigger for the activation of mast cells is more specific. In the case of dermographism (writing on the skin), mild pressure or stroking of the skin will activate the local tissue mast cells (Fig. 232-1). This type of chronic inducible urticaria is often also seen in patients with chronic spontaneous urticaria. In cholinergic urticaria, patients experience short-lived hives when their body temperature is elevated, such as with exercise. Cold-induced urticaria activates mast cells beneath a well-defined temperature threshold.

Other Subtypes

In rare cases of chronic urticaria and angioedema, a food or drug allergen is identified. In addition, contact allergens such as soaps, detergents, cosmetics, or latex may be involved. Urticaria may also occur secondary to an unrecognized autoimmune condition such as rheumatoid arthritis (Chapter 243), systemic lupus erythematosus (Chapter 245), a systemic vasculitis (Chapter 249), or thyroid disease (Chapter 207) or, extremely rarely, as a paraneoplastic skin phenomenon (Chapter 164). In endemic areas, parasitic infections with strongyloides (Chapter 327) or filariasis (Chapter 327) can be associated with urticaria.

CLINICAL MANIFESTATIONS

Urticaria (hives) is a pruritic, erythematous, papular skin lesion that can be raised, can have a pale center, and can extend from several millimeters to centimeters in size (Fig. 232-2). Each individual lesion may persist for up to 24 hours. Lesions of longer duration should raise concern for other diagnoses (Chapter 407). Angioedema is defined by the rapid onset of nonpitting edema in the subdermal or mucosal tissues without erythema or well-defined borders. Areas of angioedema can be associated with a sensation of tingling, pressure, pain, or burning. Commonly involved areas include the face, cheek, lips, tongue, hands, feet, and genitalia (Fig. 232-3). Angioedema typically does not resolve as rapidly as urticaria and can persist for up to 72 hours.

Pruritus commonly precedes and then accompanies the eruption of papular hives or wheals. Hives or wheals may be round, annular, or serpiginous; they can appear in groups, can coalesce, and also appear several times a day. The typical time course of individual hives can be 30 minutes to 24 hours before full resolution of the skin without ecchymoses.

Chronic spontaneous urticaria frequently involves areas of constant pressure (e.g., the waistband), thereby supporting overlap of chronic spontaneous urticaria with chronic inducible urticarias such as dermographism. If a patient is taking antihistamines, the lesions appear flattened. The severity of pruritus can disrupt both daytime activities and sleep. In more severe cases of chronic urticaria, extracutaneous symptoms can include headache, fatigue, wheezing, gastrointestinal complaints, or a joint pain.

Some chronic inducible urticarias present with unique clinical features.[11] In cold-induced urticaria,[12] local lesions appear when the skin is exposed to a sudden drop in air temperature or cold water. In cholinergic urticaria, the wheals appear during physical exertion and resemble smaller papules with large surrounding erythematous bases. With delayed pressure urticaria, the onset of urticaria or angioedema (e.g., hand swelling hours after carrying groceries) occurs 4 hours or longer after the pressure triggers.

ABSTRACT

Episodes of urticaria or angioedema are classified by their duration and by the presence or absence of a known trigger. Acute urticaria persists for less than 6 weeks, whereas chronic urticaria is defined by recurrent urticaria, angioedema, or both for more than 6 weeks. Chronic urticaria is further subdivided based on whether patients have chronic inducible urticaria with a specific physical stimulus for their hives (about 20% of patients) or have chronic spontaneous urticaria without a clear trigger (about 80% of patients). Chronic spontaneous urticaria can be manifested as urticaria or angioedema. Angioedema is driven by mast cells, and the histaminergic angioedema of chronic urticaria must be distinguished from the bradykinin-mediated angioedema that is observed in rare types of hereditary angioedema and related diseases. The treatments for these two disorders are distinct, as are the implications for morbidity and mortality.

FIGURE 232-3. Angioedema.

DIAGNOSIS

Urticaria is usually a clinical diagnosis based on seeing the skin lesions either in person or by a photograph (Fig. 232-4). By definition, urticaria is first subdivided into acute (<6 weeks duration) and chronic forms.

Acute Urticaria

The diagnosis of acute urticaria or angioedema requires a comprehensive history and physical examination with attention to ingestions, the pattern of the eruptions, contactants, recent infections, and review of photographs of past lesions. A history of recent infections or vaccinations and any new exposures to foods and to prescribed or over-the-counter drugs should be elicited, and any close temporal relationship to potential precipitants should be explored. To prove a link to urticaria, the suspected drug or food must be withdrawn; if the reaction is mild enough to be well-tolerated, re-challenge can then confirm the cause. In the majority of cases, however, no trigger is identified.

Chronic Urticaria

For chronic urticaria, with symptoms of 6 weeks or more, subtypes include chronic spontaneous (absence of identifiable trigger) urticaria, inducible (well-defined eliciting factor) urticaria, ingestion-related urticaria, or urticaria associated with an underlying systemic process. Other diseases to consider are generalized pruritus, flushing disorders such as carcinoid (Chapter 213), urticarial vasculitis (Chapter 407), systemic mastocytosis (Chapter 235), exercise-related anaphylaxis (Chapter 233), food-associated anaphylaxis (Chapter 233), idiopathic anaphylaxis, hereditary angioedema, acquired angioedema, angiotensin-converting enzyme (ACE) inhibitor–induced angioedema, systemic lupus erythematosus (Chapter 245), autoinflammatory disease (Chapter 240), and polymorphous eruptions of pregnancy (Table 232-1).[13] Local cold-related skin eruptions must be differentiated from cryoglobulinemia (Chapter 173) and from cryopyrin-based familial fever disorders (Chapter 240).

When angioedema involves the lip, throat, or tongue, or when patients develop abdominal pain due to intestinal mucosal swelling without urticaria, drug-induced angioedema or hereditary angioedema should be considered. In 20 to 30% of patients, ingestions such as nonsteroidal anti-inflammatory drugs (NSAIDs) can exacerbate underlying chronic spontaneous urticaria.[14]

Diagnostic Testing

The evaluation of chronic urticaria should include a complete blood count with differential, a metabolic panel, liver enzymes, a C-reactive protein (CRP) level, and an erythrocyte sedimentation rate (ESR). Additional studies, including a thyroid-stimulating hormone (TSH) level, thyroid antibodies, and an autoimmune profile, generally should be reserved for patients in whom the history, physical examination, or basic laboratory studies raise a suspicion. Skin testing for foods is not recommended given lack of evidence to support food allergy as a cause in chronic spontaneous urticaria, the high rate of false-positive tests owing to the presence of dermographism in many patients who have chronic spontaneous urticaria, and the need to withdraw antihistamines to conduct such testing. Testing for autoantibodies for IgE and the high-affinity IgE receptor is controversial because of a lack of universal standards and because such autoantibodies can be elevated in healthy patients as well as in patients who have other autoimmune diseases.

For inducible urticarias, provocative testing by a specialist can assist in confirming the diagnosis and spare exhaustive investigations. Examples include an ice cube challenge for cold urticaria or scratching the skin to check for dermographism. Some subtypes of chronic inducible urticaria, such as dermographism, are also observed in patients who have chronic spontaneous urticaria.

A skin biopsy is reserved for cases in which the diagnosis is in doubt or when urticarial vasculitis is suspected because of bruising at the site of wheals or pain rather than itch as the main symptom. For example, if lesions persist for longer than 24 hours and bruise, a skin biopsy is required to confirm or refute urticarial vasculitis. The persistence of skin discoloration on resolving lesional skin should also prompt a skin biopsy. Microscopic evidence of fibrinoid necrosis, endothelial damage, and immune deposits should lead to further search for a secondary immune disorder such as systemic lupus erythematosus (Chapter 245). In individuals who present with recurrent episodes of swelling without hives or pruritus, hereditary angioedema, acquired angioedema, and angioedema due to ACE inhibitors must be considered.

Searching for Underlying Causes

About 95% of patients with chronic spontaneous urticaria will not have an identifiable trigger or systemic illness. Foods and drugs are often suspected by the patient with chronic urticaria but are unlikely to be the cause. Persistence of skin symptoms despite eliminating the suspected trigger confirms that the urticaria has a different cause.

A secondary systemic or infectious disorder is the cause of fewer than 2% of the cases of chronic spontaneous urticaria. Such conditions can include thyroid disorders (Chapter 207) and autoimmune diseases (Chapter 236), food allergy (Chapter 233), chronic rhinosinusitis (Chapter 394), atopic dermatitis (Chapter 405),[15] and, very rarely, an underlying malignancy (Chapter 164). Infectious diseases that are associated with chronic urticaria include sinus infections, dental abscesses, *Helicobacter pylori,* and tinea pedis; however, an extensive search for an unrecognized chronic infection is not recommended.

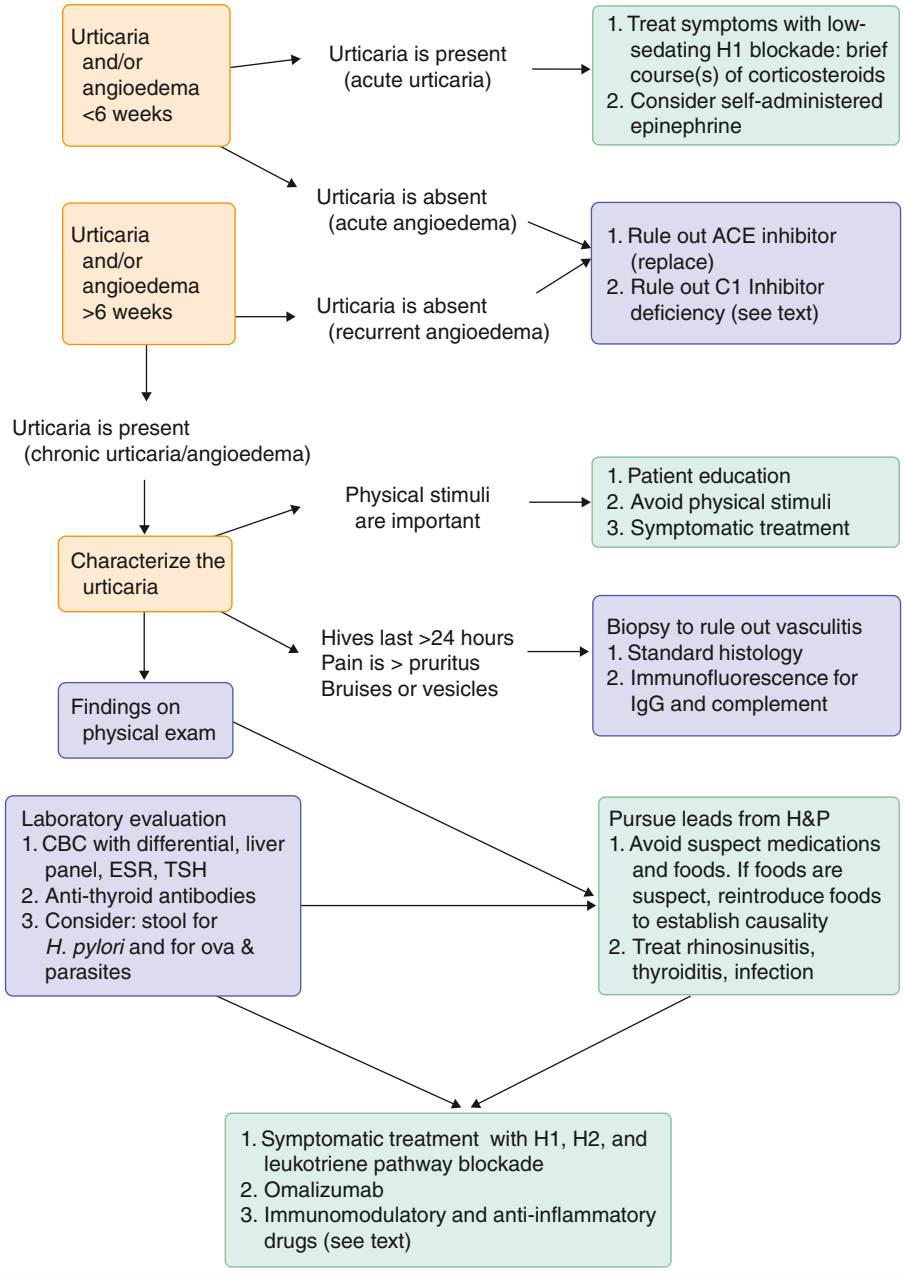

FIGURE 232-4. Evaluation and treatment of urticaria and angioedema. Treatment of urticaria with or without angioedema can be similar. However, the treatment of angioedema without urticaria depends on the cause. If the angioedema is caused by an angiotensin-converting enzyme (ACE) inhibitor, discontinuation of the medication is required. Treatment of angioedema due to deficiency or dysfunction of C1 esterase inhibitor, also called bradykinin-mediated angioedema, is discussed in the text. Recurrent angioedema is most often histaminergic but is treated as for urticaria/angioedema. CBC = complete blood count; ESR = erythrocyte sedimentation rate; H&P = history and physical examination; H1 = histamine receptor antagonist; TSH = thyroid-stimulating hormone.

TREATMENT

Acute Urticaria

Acute urticaria is self-limited and usually is responsive to antihistamines[A1] (e.g., a second-generation antihistamine such as cetirizine 10 mg, levocetirizine 5 mg, fexofenadine 180 mg, loratadine 10 mg, or desloratadine 5 mg daily). In severe cases, adding oral corticosteroids (e.g., prednisone 20 to 40 mg daily for 5 days) can provide better symptomatic relief, but intravenous corticosteroids are not beneficial.[A2] Endotracheal intubation is rarely required but is sometimes indicated in patients who have shortness of breath, drooling, and swelling of the interior tongue or pharynx.[16]

Chronic Urticaria

Treatment should begin with a second-generation antihistamine once daily, with the dose advanced, if needed, to up to four times daily at 2- to 4-week intervals.[A3,A4] NSAIDs, which can trigger episodes in up to 30% of patients, and opioids should be avoided. When these higher doses of antihistamines are unsuccessful (approximately 50% of patients), omalizumab (a monoclonal anti-IgE antibody at a dose of 300 mg every 4 weeks) should be initiated.[A5,A6] In rare severe cases of chronic spontaneous urticaria, oral corticosteroids may be tried under expert oversight. For refractory chronic urticaria, options include cyclosporine, hydroxychlorquine, sulfasalazine, dapsone, tacrolimus, and mycophenolate. Bruton tyrosine kinase inhibitors (e.g., remibrutinib) and agents that target mast cells (e.g., benralizumab, tezepelumab, and dupilumab) are under study.

PREVENTION

Patients who have chronic spontaneous urticaria are encouraged to accept that their disease is spontaneous in origin and not linked to external triggers. The therapeutic approach involves managing symptoms but does not hasten resolution of the disease. Patients who have chronic inducible urticaria are advised to avoid any identifiable triggers such as exposure to cold, hot showers, exercise, or sweating. For patients who have an identified underlying disorder, such as thyroid dysfunction or autoimmune disease, treatment of the disorder can reduce or eliminate skin symptoms.

PROGNOSIS

The prognosis for most patients with chronic spontaneous urticaria is excellent. About 50% of cases of simple urticaria resolve in 1 year, and nearly 80% resolve within 3 to 5 years. However, symptoms of chronic urticaria can recur in approximately 15% of patients even after more than 6 months without symptoms. Longer durations of disease tend to occur in patients who suffer inducible urticarias.

BRADYKININ-MEDIATED HEREDITARY ANGIOEDEMA AND RELATED DISEASES

Bradykinin-mediated angioedema, which is seen in rare types of hereditary angioedema and related diseases, must be distinguished from the mast cell–driven, histaminergic angioedema of chronic urticaria.

EPIDEMIOLOGY

Hereditary angioedema is a rare autosomal dominant disorder that affects approximately 1 in 50,000 individuals. Mutations in the *SERPING1* gene result in a deficiency of the functional C1 esterase inhibitor. Family history confirms the autosomal dominant inheritance in about 75% of cases, whereas de novo mutations likely are responsible for the other 25% of patients who lack a family history. Hereditary angioedema with normal C1 esterase inhibitor levels has a similar clinical phenotype but is more common in females.

Acquired angioedema affects older adults who often have an associated monoclonal gammopathy or underlying lymphoma. ACE inhibitor–induced angioedema occurs in approximately 0.7% of treated patients.[17] ACE inhibitor–induced angioedema is more common in Blacks and in persons who smoke tobacco. Aliskrein, which is a direct renin inhibitor, is also associated with increased risk of angioedema, as is the combination of sacubitril-valsartan.

PATHOBIOLOGY

Hereditary angioedema and acquired angioedema are related to low levels or abnormal function of the C1 esterase inhibitor, which regulates the complement (Chapter 37), fibrinolytic, and contact system (kinin-generating) pathways.[18] C1 esterase inhibitor levels and function generally must be at least 40% of normal to control the generation of kinins, but the presence of one normal gene typically results in levels that are only 5 to 30% of normal. In type I hereditary angioedema (85% of patients), the abnormal gene does not produce C1 esterase inhibitor protein. In type II hereditary angioedema (15% of patients), the C1 esterase inhibitor protein is detectable at normal levels but lacks appropriate function.

The C1 esterase inhibitor enzyme regulates cleavage of two complement products, C2 and C4. In the absence of this regulatory activity, patients with both hereditary angioedema I and II have chronic low levels of C2 and C4. However, central to the mechanism of swelling in hereditary angioedema is the inadequate regulation of the kinin pathway, thereby leading to excess production of the vasoactive mediator bradykinin. Excess bradykinin leads to vascular leak that is responsible for the episodes of swelling. A third category of hereditary angioedema, formerly called type III, is now termed hereditary angioedema with normal C1 esterase inhibitor levels. In these conditions, the levels and function of C1 esterase inhibitor protein are normal, but mutations occur in other pathways related to bradykinin.[19]

In acquired angioedema, unknown factors activate C1 esterase inhibitor protein and lead to its depletion, or autoantibodies target C1 esterase inhibitor protein and inhibit its function. ACE inhibitor–associated angioedema, which is the leading cause of the drug-induced form of acquired angioedema, is linked to the inhibition of an enzyme that is related to the breakdown of bradykinin and does not involve proteins of the complement pathway.

CLINICAL MANIFESTATIONS

The onset of hereditary angioedema types I and II is typically in the first and second decades of life. Attacks are classified as cutaneous, upper airway (laryngeal), or gastrointestinal. The skin lesions are typically nonpruritic, nonpitting, and asymmetric (Fig. 407-1). The severity of attacks worsens after puberty, with episodes that can affect all areas of the body including face and genitalia. One-third of patients report a prodromal serpiginous rash that is nonpruritic (erythema marginatum; Fig. 407-2). Swelling of the uvula and posterior pharynx can lead to life-threatening asphyxiation. More than 50% of patients can experience a laryngeal attack in their lifetime. Involvement of mucosal surfaces of the gastrointestinal tract can present as an acute abdomen and lead to unnecessary surgical interventions. Episodes of swelling typically persist for 24 to 72 hours. About 50% of patients report that local pressure or trauma can precipitate an attack. Stress can be another important trigger.

In acquired angioedema, the clinical manifestations are generally similar but are more likely to involve the facial area (see Fig. 232-3). In ACE inhibitor–induced angioedema, for example, severe swelling of the face and neck predominates. Episodes can begin during the first weeks of use but may not occur for years after therapy is initiated.

TABLE 232-1 CLASSIFICATION OF URTICARIA AND ANGIOEDEMA

ACUTE HISTAMINERGIC URTICARIA AND ANGIOEDEMA
Hypersensitivity reactions
Food allergy
Drug allergy
Insect allergy
Associated with infections (e.g., respiratory)
Non–IgE-related
Drugs: opioids, nonsteroidal anti-inflammatory drugs
Radiocontrast dye
Toxic reactions
Immune complex
Serum sickness
Transfusion related
Postviral illness
CHRONIC HISTAMINERGIC URTICARIA AND ANGIODEMA
Spontaneous
Autoantibody associated
IgG anti-IgE
IgG anti-IgE receptor (FceRI)
IgG anti-thyroid antigens
Other
Non-autoantibody associated
Inducible
Dermographism
Cholinergic
Cold-induced
Delayed pressure
Solar
Vibratory
Aquagenic
Immune complex
Urticarial vasculitis
Autoimmune disease associated
URTICARIA PIGMENTOSA AND SYSTEMIC MASTOCYTOSIS (see Chapter 235)
KININ-MEDIATED ANGIOEDEMA
Hereditary angioedema
Acquired angioedema
Angiotensin-converting enzyme–induced angioedema
Renin inhibitor induced angioedema

IgE = immunoglobulin E; IgG = immunoglobulin G.

DIAGNOSIS

The key to the diagnosis is the direct measurement, especially during an attack, of C1 esterase inhibitor protein (antigen test) and function, as well as levels of C4.[20] Features that distinguish acquired angioedema from hereditary angioedema are onset of symptoms later in life (age >40 years) or presence of an underlying malignancy, such as B-cell lymphoma (Chapter 171) or plasma cell dyscrasia (Chapter 173). Depressed levels of C1q are seen only in acquired hereditary angioedema.

In ACE inhibitor–induced angioedema, all of these test results are typically normal. Patients with normal C1 hereditary angioedema also have normal test results and an absence of hives. Patients who have histaminergic rather than bradykinin-mediated angioedema also have normal test results but respond to antihistamines and corticosteroids. The lack of response to antihistamines and corticosteroids distinguishes the bradykinin-mediated disorders that are associated with normal C1 esterase inhibitor levels and function from patients who have histaminergic angioedema. In such patients, measurement of serum immunoglobulin can exclude a plasma cell dyscrasia, but a detailed search for an occult lymphoma is not routinely indicated.

TREATMENT AND PREVENTION

The therapies for hereditary angioedema include on-demand treatment of attacks as well as prophylactic therapies, preferably as part of a personalized care plan developed with a specialist.[21]

Hereditary Angioedema

Acute Attacks

First-line treatment for an acute attack of hereditary angioedema is self-injection of a bradykinin 2 receptor antagonist (icatibant, 30 mg subcutaneously) or a kallikrein inhibitor that blocks the production of bradykinin (ecallantide, 30 mg subcutaneously). Another option is to replace the C1 esterase inhibitor protein by the infusion of

a C1 esterase inhibitor concentrate (20 units/kg) or human recombinant C1 esterase inhibitor (50 units/kg), but early self-treatment at home leads to better control of the episode. By comparison, the clinical response to epinephrine, antihistamines, or corticosteroids is poor. If neither C1 esterase inhibitor replacement therapy nor bradykinin antagonists are available, 2 units of fresh frozen plasma can replace the depleted C1 esterase inhibitor levels but at the potential risk of supplying substrates that could increase kinin levels.[22] Treating physicians must be prepared to perform intubation or tracheostomy if patients do not respond promptly to medical therapies.

Chronic Therapy

If a patient has mild disease or infrequent attacks, patients may be treated with only on-demand therapies as outlined above. For more severe or frequent symptoms, subcutaneous replacement with plasma-derived C1 esterase inhibitor (60 IU/kg twice weekly) is an option.[A7] An oral kallikrein inhibitor (berotralstat, 150 mg daily)[A8] or subcutaneous lanadelumab (an antibody that inhibits kallikrein at 300 mg every 2 to 4 weeks)[A9] can reduce the frequency and severity of attacks. Another option is replacement C1 esterase inhibitor concentrate (1000 units intravenously every 3 to 4 days). ACE inhibitors and estrogens should be avoided because of their potential to exacerbate episodes of angioedema.

Danazol (50 mg to 200 mg up to twice daily), which can increase the production of C1 esterase inhibitor and reduce symptoms, is a second-line option in settings in which more specific therapies are unavailable. Androgen therapy can cause virilizing effects and liver complications, and it is contraindicated during pregnancy.

Short-term Prophylaxis

Because trauma is a known trigger for attacks, patients should be treated prophylactically before certain medical procedures. For dental surgery, which is associated with oral swelling that can progress to airway obstruction, short-term prophylaxis with a single dose of C1 esterase inhibitor replacement 1 to 12 hours before the procedure is effective. An alternative is to use danazol for 5 to 7 days before the procedure and continue it for 2 to 5 days afterward.

Acquired Angioedema

Acquired angioedema is approached in a fashion similar to that for hereditary angioedema, but definitive treatment is linked to therapy of the underlying disease.

ACE Inhibitor–Induced Angioedema

Treatment of ACE inhibitor–induced angioedema involves acute airway management and discontinuation of the ACE inhibitor. Icatibant is of uncertain value.[23] Shifting to an angiotensin receptor blocker is typically well tolerated.

PROGNOSIS

The long-term prognosis for patients with hereditary angioedema depends on the phenotype, frequency of episodes, and access to advanced agents both for acute episodes and prophylaxis. Repeated use of therapeutic and preventive medicines appears to be safe, but long-term danazol treatment should be avoided if possible. Life expectancy should be normal given access to advanced treatments. The outlook for acquired angioedema is affected by the prognosis of the underlying disease. ACE inhibitor–induced angioedema is normally self-limited and responds to its discontinuation.

233 ANAPHYLAXIS

LAWRENCE B. SCHWARTZ AND MARIANA CASTELLS

DEFINITION

Anaphylaxis arises when mast cells and possibly basophils secrete potent mediators that have effects on vasculature, smooth muscle, mucous glands, and nerves, thereby eliciting a systemic response.[1] Although mast cells in any organ system may be involved, dictated in part by the distribution of the instigating stimulus, the principal targets are the cardiovascular, cutaneous, respiratory, and gastrointestinal systems, where mast cells are most abundant. Anaphylaxis occurs when mast cells are activated by multivalent allergens that bind to and aggregate immunoglobulin E (IgE) and high-affinity IgE receptors (FcεRI) on their surfaces. These activated mast cells then secrete mediators, such as histamine, tryptase, prostaglandin d4, and leukotriene c4, that cause the systemic symptoms of immediate hypersensitivity.

EPIDEMIOLOGY

Approximately 1500 to 2000 deaths are attributed to anaphylaxis annually in the United States.[2] Anaphylaxis to foods and insect stings each account for about 100 deaths per year.

The lifetime incidence of anaphylaxis in adults is estimated at 2 to 8%. In children, in whom food allergy is more common, the incidence of anaphylaxis is likely higher. More than 80% of physicians practicing allergy/immunology, emergency medicine, general medicine, or pediatrics report having witnessed anaphylaxis. Medications, insect stings, and foods are the most common triggers, followed by environmental allergens and latex (Table 233-1). In some cases, the cause of anaphylaxis is unknown. About 50% of the reactions occur at home, 15% at a medical facility, and 6 to 7% at another person's home, at work, or at a restaurant. Antibiotics and radiocontrast media are the most commonly identified triggers in hospitals, and COX-1 inhibitor nonsteroidal anti-inflammatory drugs (NSAIDs) are a leading cause of anaphylaxis seen in emergency departments.[3] Chemotherapy agents (Chapter 234) and monoclonal antibodies also are common causes of anaphylaxis.[4] In the perioperative setting, anaphylactic reactions occur with a frequency of about 1 in 2000 to 10,000 cases.[5] Muscle relaxants or antibiotics are the most common triggers, but latex, induction drugs, chlorhexidine, and other agents also can be the culprit. Advanced age, use of a β-blocker or angiotensin pathway inhibitor, hereditary α-tryptasemia, and concomitant mastocytosis (Chapter 235) increase the risk for severe anaphylaxis. Hereditary α-tryptasemia, which is caused by an increased copy number of the gene that encodes α-tryptase, may be present in up to 5% of the population.[6]

Some type of food allergy is self-reported in 19% of adults and likely is present in as many as 11%, but only about half of these allergies are classified as serious. About 20% of children lose peanut sensitivity by school age, but a small portion will regain peanut sensitivity later in life, particularly if they continue to avoid this food. Most children lose their allergic sensitivities to cow's milk, egg, wheat, or soy by 5 years of age, whereas sensitivities to tree nuts and seafoods are typically persistent.

Latex provokes anaphylaxis in a small but significant group of individuals, particularly patients who have undergone multiple surgical procedures early in life and individuals with frequent exposures later in life, such as medical personnel. Estimates of the prevalence of latex hypersensitivity range from

a C1 esterase inhibitor concentrate (20 units/kg) or human recombinant C1 esterase inhibitor (50 units/kg), but early self-treatment at home leads to better control of the episode. By comparison, the clinical response to epinephrine, antihistamines, or corticosteroids is poor. If neither C1 esterase inhibitor replacement therapy nor bradykinin antagonists are available, 2 units of fresh frozen plasma can replace the depleted C1 esterase inhibitor levels but at the potential risk of supplying substrates that could increase kinin levels.[22] Treating physicians must be prepared to perform intubation or tracheostomy if patients do not respond promptly to medical therapies.

Chronic Therapy

If a patient has mild disease or infrequent attacks, patients may be treated with only on-demand therapies as outlined above. For more severe or frequent symptoms, subcutaneous replacement with plasma-derived C1 esterase inhibitor (60 IU/kg twice weekly) is an option.[A7] An oral kallikrein inhibitor (berotralstat, 150 mg daily)[A8] or subcutaneous lanadelumab (an antibody that inhibits kallikrein at 300 mg every 2 to 4 weeks)[A9] can reduce the frequency and severity of attacks. Another option is replacement C1 esterase inhibitor concentrate (1000 units intravenously every 3 to 4 days). ACE inhibitors and estrogens should be avoided because of their potential to exacerbate episodes of angioedema.

Danazol (50 mg to 200 mg up to twice daily), which can increase the production of C1 esterase inhibitor and reduce symptoms, is a second-line option in settings in which more specific therapies are unavailable. Androgen therapy can cause virilizing effects and liver complications, and it is contraindicated during pregnancy.

Short-term Prophylaxis

Because trauma is a known trigger for attacks, patients should be treated prophylactically before certain medical procedures. For dental surgery, which is associated with oral swelling that can progress to airway obstruction, short-term prophylaxis with a single dose of C1 esterase inhibitor replacement 1 to 12 hours before the procedure is effective. An alternative is to use danazol for 5 to 7 days before the procedure and continue it for 2 to 5 days afterward.

Acquired Angioedema

Acquired angioedema is approached in a fashion similar to that for hereditary angioedema, but definitive treatment is linked to therapy of the underlying disease.

ACE Inhibitor–Induced Angioedema

Treatment of ACE inhibitor–induced angioedema involves acute airway management and discontinuation of the ACE inhibitor. Icatibant is of uncertain value.[23] Shifting to an angiotensin receptor blocker is typically well tolerated.

PROGNOSIS

The long-term prognosis for patients with hereditary angioedema depends on the phenotype, frequency of episodes, and access to advanced agents both for acute episodes and prophylaxis. Repeated use of therapeutic and preventive medicines appears to be safe, but long-term danazol treatment should be avoided if possible. Life expectancy should be normal given access to advanced treatments. The outlook for acquired angioedema is affected by the prognosis of the underlying disease. ACE inhibitor–induced angioedema is normally self-limited and responds to its discontinuation.

233 ANAPHYLAXIS

LAWRENCE B. SCHWARTZ AND MARIANA CASTELLS

DEFINITION

Anaphylaxis arises when mast cells and possibly basophils secrete potent mediators that have effects on vasculature, smooth muscle, mucous glands, and nerves, thereby eliciting a systemic response.[1] Although mast cells in any organ system may be involved, dictated in part by the distribution of the instigating stimulus, the principal targets are the cardiovascular, cutaneous, respiratory, and gastrointestinal systems, where mast cells are most abundant. Anaphylaxis occurs when mast cells are activated by multivalent allergens that bind to and aggregate immunoglobulin E (IgE) and high-affinity IgE receptors (FcεRI) on their surfaces. These activated mast cells then secrete mediators, such as histamine, tryptase, prostaglandin d4, and leukotriene c4, that cause the systemic symptoms of immediate hypersensitivity.

EPIDEMIOLOGY

Approximately 1500 to 2000 deaths are attributed to anaphylaxis annually in the United States.[2] Anaphylaxis to foods and insect stings each account for about 100 deaths per year.

The lifetime incidence of anaphylaxis in adults is estimated at 2 to 8%. In children, in whom food allergy is more common, the incidence of anaphylaxis is likely higher. More than 80% of physicians practicing allergy/immunology, emergency medicine, general medicine, or pediatrics report having witnessed anaphylaxis. Medications, insect stings, and foods are the most common triggers, followed by environmental allergens and latex (Table 233-1). In some cases, the cause of anaphylaxis is unknown. About 50% of the reactions occur at home, 15% at a medical facility, and 6 to 7% at another person's home, at work, or at a restaurant. Antibiotics and radiocontrast media are the most commonly identified triggers in hospitals, and COX-1 inhibitor nonsteroidal anti-inflammatory drugs (NSAIDs) are a leading cause of anaphylaxis seen in emergency departments.[3] Chemotherapy agents (Chapter 234) and monoclonal antibodies also are common causes of anaphylaxis.[4] In the perioperative setting, anaphylactic reactions occur with a frequency of about 1 in 2000 to 10,000 cases.[5] Muscle relaxants or antibiotics are the most common triggers, but latex, induction drugs, chlorhexidine, and other agents also can be the culprit. Advanced age, use of a β-blocker or angiotensin pathway inhibitor, hereditary α-tryptasemia, and concomitant mastocytosis (Chapter 235) increase the risk for severe anaphylaxis. Hereditary α-tryptasemia, which is caused by an increased copy number of the gene that encodes α-tryptase, may be present in up to 5% of the population.[6]

Some type of food allergy is self-reported in 19% of adults and likely is present in as many as 11%, but only about half of these allergies are classified as serious. About 20% of children lose peanut sensitivity by school age, but a small portion will regain peanut sensitivity later in life, particularly if they continue to avoid this food. Most children lose their allergic sensitivities to cow's milk, egg, wheat, or soy by 5 years of age, whereas sensitivities to tree nuts and seafoods are typically persistent.

Latex provokes anaphylaxis in a small but significant group of individuals, particularly patients who have undergone multiple surgical procedures early in life and individuals with frequent exposures later in life, such as medical personnel. ABSTRACT

Anaphylaxis arises when mast cells and possibly basophils secrete potent vasoactive mediators (such as tryptase, histamine, leukotriene C4, and prostaglandin D2) that dilate smooth muscle and increase the secretion of mucus, thereby eliciting a systemic response in multiple organ systems. With a lifetime incidence of 2 to 8%, this potentially fatal condition is more common than previously appreciated. Triggers may include medications, insect stings, foods, or latex. Typically, anaphylaxis occurs when these allergens bind to IgE and lead to aggregation of the high-affinity IgE receptor on the plasma membrane, but spontaneous triggering also occurs. Anaphylaxis is sometimes associated with an underlying clonal mast cell disorder, such as a somatic gain-of-function mutation of *c-KIT* or an increased copy number of the gene encoding α-tryptase. Clinical criteria, including concurrent signs and symptoms in at least two organ systems (cutaneous, gastrointestinal, pulmonary, and cardiovascular systems), facilitate the diagnosis of anaphylaxis in real time. Laboratory tests, including an elevated acute versus baseline serum tryptase level, can support the clinical diagnosis. Appropriate acute interventions (supine positioning and timely administration of epinephrine) and preventive therapies (insect venom immunotherapy and anti-IgE medications) can be lifesaving.

1 to 6% in the general population and about 10% among regularly exposed health care workers. Each year, latex-induced anaphylaxis occurs in about 200 individuals and causes an average of 3 deaths. The majority of children labeled as penicillin allergic lose their sensitivity as adults.

PATHOBIOLOGY

The mediators produced by activated mast cells and basophils initiate many of the signs and symptoms of anaphylaxis. These cells constitutively express the high affinity receptor for IgE, FcεRI, on their surface, thereby enabling these cells to be armed by antigen-specific IgE and triggered by antigens that aggregate IgE:FcεRI complexes. In addition to mast cells and basophils, other cells that likely participate in anaphylaxis include eosinophils, monocytes, antigen-presenting cells, platelets, and epithelial cells.

Most IgE-dependent mast cell activation events occur at local sites and result in local disease, such as allergic conjunctivitis, rhinitis, or asthma when allergens land on the corresponding mucosal surface of a sensitive individual and diffuse into the tissue where mast cells reside. Anaphylaxis presumably requires the allergen (or nonallergen agonist) to distribute systemically to activate mast cells at remote sites. However, activation of the contact system by mast cell products (e.g., heparin or tryptase) results in the production of bradykinin, which may also enhance the severity of anaphylaxis. Impaired metabolism of the mast cell mediator platelet-activating factor also may enhance severity.

Allergens

Most allergens are proteins or glycoproteins that serve as complete antigens, have at least two epitopes that are recognized by different IgE antibodies, and thereby are capable of aggregating IgE in a sensitized subject. The protease activity of some allergens (e.g., house dust mite Der p1) may facilitate their penetration and allergenicity at mucosal sites. Other allergens (e.g., Der p2) have lipid-binding domains that increase their antigenic potency. IgE anti–α-gal sensitization is elicited by Lone Star tick bites, most commonly found in the southeastern, mid-Atlantic, and midwestern states, but also throughout the world.

In contrast to complete antigens, most drugs act as haptens. The drugs become covalently linked to self-proteins in the circulation, in tissues, or on cells and become multivalent allergens that are able to bind and aggregate IgE:FcεRI to activate mast cells. Injected chemotherapy drugs such as platins are common drug allergens that act as haptens. Monoclonal antibodies, in particular chimeric antibodies carrying nonhuman sequences such as rituximab, can bind IgE as complete antigens and trigger anaphylaxis.[7]

Exposure to an allergen must first lead to sensitization before an immediate hypersensitivity reaction can occur. This process, which requires at least 1 week, involves antigen processing by antigen-presenting cells, which then present peptide antigens to T_H2 cells (T helper lymphocytes), which in turn instruct allergen-specific B cells to switch from production of allergen-specific IgM or IgG to IgE. Production of IL-4 or IL-13 by T_H2 cells and binding of T_H2 CD40 ligand to B cell CD40 are essential for this antibody class switch. Consequently, anaphylaxis does not occur on first exposure to an allergen (sensitization phase), because the antigen is likely gone by the time antigen-specific IgE is made, but can occur with subsequent exposures. Cross-sensitization can occur with foods or medications that contain the same or similar allergenic components, and patients can react at first exposure when previously exposed and sensitized to a related substance.

Food

Most cases of food-induced anaphylaxis in children occur in response to eggs, peanuts, cow's milk, wheat, or soy, whereas peanuts, tree nuts, sesame seeds, and seafood account for most reactions in adults.[8] An oral allergy syndrome typically occurs when individuals who are sensitive to pollen allergens eat a food that cross-reacts with it, such as when ragweed pollen IgE cross-reacts with melon or when birch pollen IgE cross-reacts with a peach or apple. Such food allergen epitopes are typically conformational (rather than linear) and more easily destroyed by heat when cooked, by acid in the stomach, or by proteases in the intestines, so they rarely progress to systemic reactions.

Food allergy–associated exercise-induced anaphylaxis occurs when sensitive subjects exercise within several hours after eating the food allergen but does not occur when the food is eaten without exercise. Shrimp and wheat are most commonly implicated.[9] Exercise appears to increase intestinal permeability to food antigens, which then enter into the systemic circulation. Aspirin, other nonsteroidal anti-inflammatory drugs, and alcohol also act to increase intestinal permeability and may help trigger food-induced anaphylaxis.

Insect Sting Venom

Hymenoptera families primarily responsible for sting venom-triggered anaphylactic reactions include the Apidae (honey bees and bumble bees), Vespidae (hornets, yellow jackets, and paper wasps), and Formicidae (fire ants).[10] Major allergens of honey bees include phospholipase A_2 (Api m 1), hyaluronidase (Api m 2), and melittin (Api m 4). Bumble bee venom proteins exhibit immunologic cross-reactivity with those of the honey bee but lack melittin. Vespid venoms cross-react among themselves and include phospholipase and hyaluronidase, the latter allergen cross-reacting with bee hyaluronidase. Fire ant venom contains various alkaloids that are not allergenic but produce sterile pustules and various allergenic proteins that cross-react with vespid allergens, such as phospholipase and scorpion venom allergens. If previously sensitized to cross-reactive venom from a different insect, a person may exhibit an anaphylactic reaction on first exposure to one insect sting. Allergens from biting insects of the Diptera order (mosquitoes, gnats, midges, true flies) are salivary in origin and do not cross-react with Hymenoptera venom allergens. Anaphylaxis to these salivary proteins appears to be uncommon, but precise epidemiologic data are problematic because people are often unaware of a mosquito bite, and commercial diagnostic reagents of high quality are not yet available.

Medications

Anaphylaxis to antibiotics including penicillin is rare, and most patients tend to lose their IgE sensitivity by 10 or more years after the initial reaction.[11] Drug allergies are described in Chapter 234.

Latex

Latex allergenic proteins are derived from the rubber tree, *Hevea brasiliensis*. Irritant dermatitis is the most frequent contact reaction and does not involve acquired immunity. Contact hypersensitivity, which results from cell-mediated immunity to haptenic chemicals used to process latex, produces a poison ivy–like local reaction that may begin the day after a sensitive subject is exposed. In contrast, IgE-dependent immediate hypersensitivity occurs against latex proteins that are present in elastic materials, catheters, balloons, and powdered latex gloves.[12] IgE-mediated cross-reactions occur between IgE anti–latex allergens and allergens in fresh foods such as bananas, chestnuts, avocados, kiwi, peaches, bell peppers, and tomato, and affected individuals may need to avoid these foods.

Vaccines

Anaphylaxis to vaccines is rare, occurring in about 1.3 per million recipients.[13] Anaphylaxis to influenza vaccine, which occurs in about 1.3 to 1.9 per million recipients, seems unrelated to a history of egg allergy. Instead, vaccine-triggered anaphylaxis may relate to sensitivities to a variety of vaccine components. Anaphylaxis to COVID-19 RNA vaccines reportedly occurs in about 1 in 100,000 recipients, typically upon first exposure, mostly in persons who have a history of anaphylaxis to other agents or foods, and more often in females than males.[14]

Non–IgE-Dependent Agonists

Many non–IgE-dependent activators of mast cells do not require processing and can elicit a response on first exposure. Examples include radiocontrast dyes, vancomycin, and most narcotics except for fentanyl. Radiocontrast dyes of low ionic strength and iso-osmolarity are less likely to elicit a systemic reaction. Vancomycin produces a non–IgE-dependent mast cell activation event known as "red man syndrome," typically involving pruritic flushing, but without cardiovascular compromise unless infused too rapidly. These reactions are usually avoided by reducing the rate of administration of the antibiotic, thereby reducing peak levels.

Endogenous mast cell activators include neuropeptides such as substance P, neurokinin A, calcitonin gene-related peptide, defensins, and the complement anaphylatoxins C3a and C5a. Although C3a and C5a each have their own receptor on mast cells, neurokinins, vancomycin, and narcotics activate a G protein–coupled receptor that is selectively expressed on mast cells, called Mas-related G protein–coupled receptor X2 (MRG-X2), thereby causing histamine secretion.

Aspirin and Nonsteroidal Anti-inflammatory Drugs

Aspirin hypersensitivity typically manifests as either a respiratory reaction with bronchospasm, nasal congestion, and rhinorrhea or a cardiovascular reaction with hypotension and urticaria. Sometimes overlap occurs with gastrointestinal signs and symptoms. In most cases, such reactions appear to be pharmacologically (not IgE) mediated, and in sensitive subjects, reactions can occur in response to any of the cyclooxygenase 1 (COX1) inhibitors. COX2-selective inhibitors appear to be safe in aspirin-intolerant asthmatic patients but not

always in patients who have cardiovascular reactions. Less commonly, sensitivity occurs to only one of the drugs within this class and is a clue that IgE against a unique chemical moiety on that particular drug is involved.

Physical Stimuli

In some individuals, urticaria or anaphylaxis can occur in response to exercise, heat, solar radiation, vibration, pressure, or cold. In some cases of familial cold- or vibration-triggered urticaria (Chapter 232), genetic defects are found.[15]

Autoimmunity, Activating Kit Mutations, and Hereditary α-Tryptasemia

Some patients experience spontaneous bouts of anaphylaxis without an obvious exogenous stimulus. Individuals with mastocytosis (Chapter 235) and hereditary α-tryptasemia are particularly prone to anaphylaxis, likely due to an excess of mast cells, the presence of mast cells that are more readily activated, enhanced tissue response to mast cell mediators, and/or the overexpression of α-tryptase. A corollary of this is that anaphylaxis to a Hymenoptera insect sting may be a presenting manifestation of these conditions.[16] A related disorder, mast cell activation syndrome, includes patients who have clonal mast cell disease, reflected by these same Kit mutations (but do not meet diagnostic criteria for systemic mastocytosis). Hereditary α-tryptasemia is an autosomal dominant disorder due to extra copies of the *TPSAB1* gene, which leads to an elevated baseline serum tryptase level (8-100 ng/mL).

Some cases of chronic urticaria are associated with IgG and IgM autoantibodies against FcεRI or IgE. Human mast cells also express FcγRIIa, which is a low-affinity IgG receptor, and FcγRI, which is the high affinity IgG-receptor. When aggregated by IgG immune complexes, either of these receptors is capable of activating mast cells and may contribute to some episodes of anaphylaxis.

CLINICAL MANIFESTATIONS

Anaphylaxis is manifested by a feeling of pruritus, lightheadedness, sweating, anxiety, confusion, nausea, and/or vomiting, accompanied by tachycardia, hypotension, and ultimately cardiovascular collapse. These symptoms and signs appear within seconds or minutes after exposure to the precipitating allergen. Respiratory or cutaneous symptoms occur in more than 50% of cases, whereas cardiovascular, neurologic, or gastrointestinal symptoms are recognized in less than 50% of cases. Most fatal anaphylactic reactions to injected venom proteins begin within 30 minutes after the sting. Most fatal food and insect sting reactions and many drug reactions are preceded by a mild immediate hypersensitivity reaction to the same allergen.

Sensitized individuals can present with delayed anaphylactic reactions 2 to 8 hours after ingestion of α-gal–containing red meats, perhaps due to transformation during digestion of monovalent to polyvalent α-gal allergens. Autoimmune progesterone-mediated anaphylaxis (progestogen hypersensitivity or catamenial anaphylaxis) tends to occur at the time of a premenstrual progesterone surge.

DIAGNOSIS

Anaphylaxis can be diagnosed clinically in real time by consensus criteria (Fig. 233-1) and by an elevated serum tryptase level. Acute concurrent onset of cutaneous signs of immediate hypersensitivity along with either hypotension or respiratory compromise in the apparent absence of allergen exposure; rapid onset of hypersensitivity signs involving at least two organs from among cutaneous, gastrointestinal, respiratory, and cardiovascular systems after exposure to a likely allergen; or rapid onset of hypotension after exposure to a known allergen.[17] Although exposure to a potential allergen should always be investigated, 30 to 60% of cases that first appear in adulthood are idiopathic and occur without a known allergen.[18]

Antigen-specific IgE, indicating sensitization, is precisely measured by either blood or skin tests. These tests should be delayed for at least 2 weeks after an anaphylactic event to prevent false-negative results. IgE sensitization is necessary but not sufficient to diagnose allergic disease, because many subjects who are sensitized to an aeroallergen, particularly at a low antigen-specific IgE level, do not have symptoms when exposed. When food allergy is suspected but not confirmed by IgE testing, oral food challenges can be performed under expert oversight,[19] using protocols to minimize the risk for severe anaphylaxis. Food-allergic reactions involving IgE should be distinguished from a variety of other types of adverse reactions, including lactose intolerance, food-induced enterocolitis (T-cell responses to cow's milk, soy, or grains), and celiac disease (Chapter 126).

An elevated serum tryptase level (normal 1 to 11 ng/mL), which peaks 30 to 120 minutes after the onset of signs or symptoms of anaphylaxis and then declines with a half-life of about 2 hours, indicates that mast cell activation has occurred. For confirmation, a level of at least $2 + 1.2 \times$ a baseline serum tryptase level measured at least 24 hours after all clinical signs and symptoms have resolved or prior to their onset is considered clinically significant. Although an increased serum total tryptase level is quite specific for anaphylaxis, its sensitivity is low for detecting anaphylaxis triggered by food ingestion and for detecting modest (no hypotension) or local (laryngeal edema) anaphylaxis. Baseline levels are above 20 ng/mL in most patients with systemic mastocytosis (Chapter 235) and above 7 ng/mL in all patients with hereditary α-tryptasemia. Elevated baseline tryptase levels correlate with an increased risk for severe insect sting–triggered anaphylaxis, likely due to the higher prevalence of a clonal mast cell disorder with an activating c-kit mutation or to increased copies of the gene encoding α-tryptase.

A patient who presents with severe life-threatening reactions to Hymenoptera venom may have an underlying clonal mast cell activation disorder such as

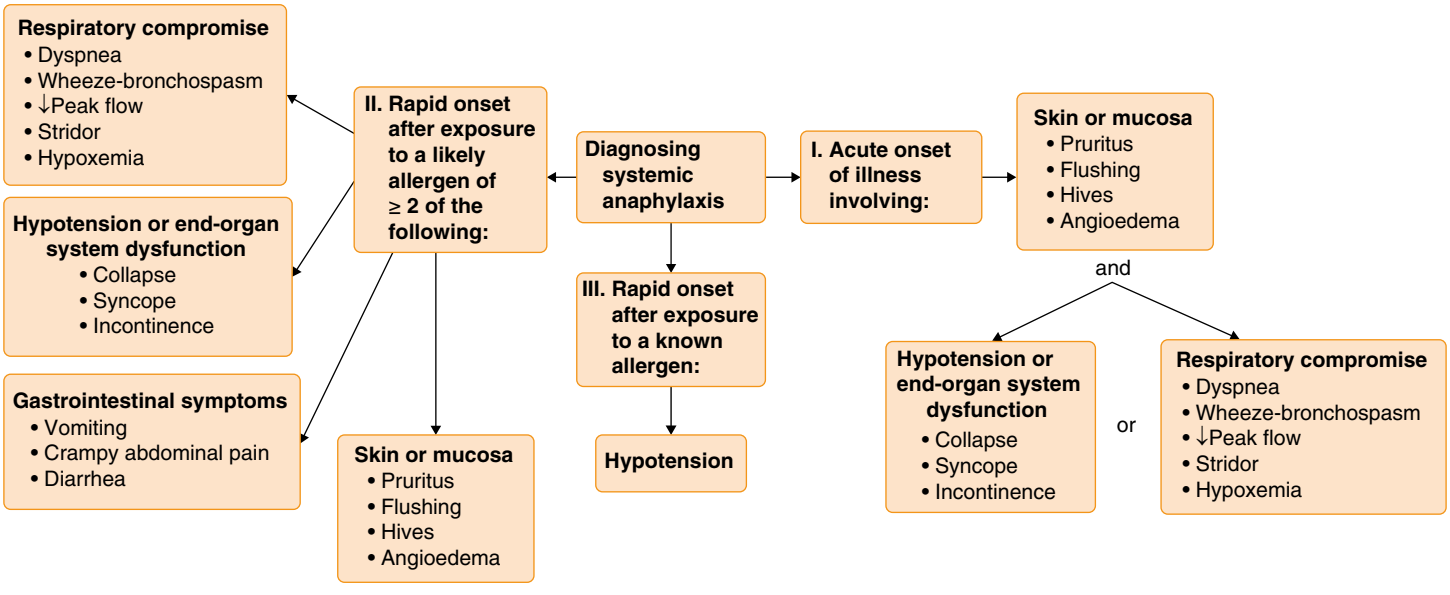

FIGURE 233-1. Diagnosing systemic anaphylaxis in a clinical setting. Acute onset of systemic anaphylaxis in the apparent absence of allergen exposure means that the signs and symptoms, once they begin, develop over minutes to an hour, while rapid onset after exposure to a likely or known allergen means that these signs and symptoms begin to occur within minutes to several hours after that exposure. (From Sampson HA, Muñoz-Furlong A, Campbell RL, et al. Second symposium on the definition and management of anaphylaxis: summary report—second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *J Allergy Clin Immunol*. 2006;117:391-397.)

mastocytosis (Chapter 235) or a genetic trait such as hereditary α-tryptasemia. Plasma and urinary histamine levels are less helpful as diagnostic biomarkers because of histamine's short half-life, its presence in histamine-containing foods, its production by histamine-producing mucosal bacteria, and the variability in histamine metabolism.

Use of an angiotensin-converting enzyme (ACE) inhibitor or of a nonselective β-blocker have been associated with more severe anaphylaxis. Low serum levels of platelet-activating factor acetyl hydrolase also have been associated with more severe cases of anaphylaxis.

Differential Diagnosis

Anaphylaxis should be distinguished from a variety of disorders with overlapping presentations. Vasovagal syncope (Chapter 49) causes diaphoresis, nausea, hypotension, and bradycardia, but without urticaria and tachycardia. Flushing disorders may be benign and unrelated to anaphylaxis, or they could be a manifestation of pathologic conditions such as the carcinoid syndrome (Chapter 213), with which urticaria and profound hypotension are not typically associated; pheochromocytoma (Chapter 209), which causes episodic hypertension; or VIPomas (Chapter 213), which cause facial flushing and voluminous diarrhea with hypokalemia but not episodic hypotension or urticaria. Panic attacks (Chapter 362) and vocal cord dysfunction may be difficult to distinguish from anaphylaxis, especially by history alone. Acute attacks of angioedema caused by C1 esterase inhibitor deficiency (Chapter 232) are not associated with pruritus or urticaria, and they evolve slower and persist longer than attacks of anaphylaxis. Shock due to the activation of complement or of the contact system, thereby leading to the production of bradykinin, can occur without activation of mast cells. Scombroidosis (Chapter 98) occurs 5 to 60 minutes after ingestion of histamine, typically in poorly stored fish, and manifests with flushing, palpitations, headache, and gastrointestinal symptoms. Acute serum sickness (Chapter 36), various cell activation syndromes, endotoxin-mediated septic shock (Chapter 94), and superantigen-mediated toxic shock syndromes (Chapters 267 and 269) manifest with fever, which is not characteristic of anaphylaxis by itself. Also, hypoglycemia (Chapter 211), seizures (Chapter 372), and pulmonary embolism (Chapter 68) or other acute cardiac events (Chapter 57) should be considered. In some cases, anaphylaxis may provoke another disorder (e.g., myocardial infarction [Chapter 58], with acute elevation of serum levels of both tryptase and troponin).

Systemic mastocytosis (Chapter 235) and hereditary α-tryptasemia are important conditions to consider in the setting of anaphylaxis. Hereditary α-tryptasemia is an autosomal dominant disorder associated with increased copy numbers of the *TPSAB1* gene, but only when it encodes α-tryptase. Hereditary α-tryptasemia can present with multiple-organ signs and symptoms including cutaneous flushing, pruritus, vibratory urticaria, dysautonomia with irritable bowel syndrome, hyperextensible joints, severe anaphylaxis, and/or retained primary dentition, often with a positive family history. Both disorders can present with anaphylaxis, particularly when spontaneous or when elicited by an insect sting, and each can be precisely diagnosed by specific genetic tests.

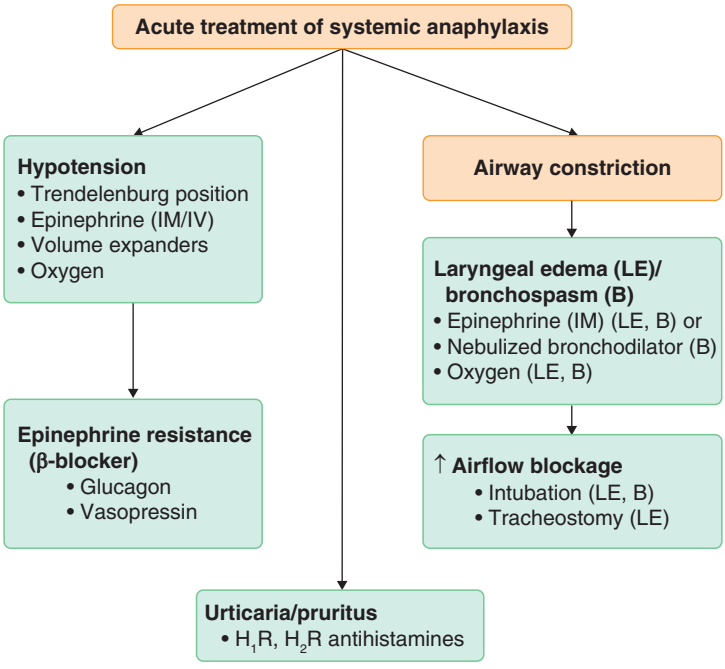

FIGURE 233-2. Acute treatment of systemic anaphylaxis. B = bronchospasm; H_1R = H_1 histamine receptor; H_2R = H_2 histamine receptor; IM = intramuscular; IV = intravenous; LE = laryngeal edema.

TREATMENT

Fatal outcomes in anaphylaxis are principally the result of either airway constriction or hypotension. Accordingly, the acute treatment of anaphylaxis requires that airway patency, blood pressure, and cardiac status be addressed (Fig. 233-2). Intubation, tracheostomy, volume expanders, and vasopressors may be needed (Chapter 92). Patients who exhibit any signs or symptoms of hypotension should immediately assume a supine position with their lower extremities slightly elevated, because almost all hypotensive anaphylactic deaths are preceded by syncope that occurs in a sitting or upright posture. Epinephrine injected intramuscularly into the thigh (0.2 to 0.5 mg for adults, 0.01 mg/kg up to 0.3 mg for children, repeated every 5 to 30 minutes as indicated) is the most effective drug, the earlier during the course of an anaphylactic event the better.[20,21] Calibrated intravenous administration of a solution of epinephrine (1 mg/100 mL solution starting at 30 to 100 mL/hour) and titrated to the lowest effective rate of infusion) can be considered in exceptional cases that do not respond to intramuscular epinephrine. Epinephrine relaxes bronchial smooth muscle and improves vascular tone and permeability, thereby counteracting bronchospasm, hypotension, and tissue edema. Although no absolute contraindication exists for the use of epinephrine to treat anaphylaxis, its benefits should be weighed against its disadvantages in elderly patients and in patients who have cerebrovascular or coronary artery disease, hypertension, diabetes, hyperthyroidism, cardiomyopathy, or narrow-angle glaucoma, in whom adverse events such as myocardial infarction, stroke, or pulmonary edema can be precipitated. Patients who are taking a β-blocker, particularly a nonselective β-blocker, may be resistant to epinephrine; in such cases, glucagon (1 mg intravenously [IV], or 1 to 5 mg/hour IV) or vasopressin (5 to 40 IU IV) may be used. Oxygen should be administered by nasal cannula. Inhaled bronchodilators can relieve bronchospasm.

Parenteral administration of H_1-receptor (diphenhydramine, 1 to 2 mg/kg up to 50 mg) and H_2-receptor (ranitidine, 300 mg IV over 5 minutes) antihistamines may prevent progression of urticaria and pruritus but is not likely to reverse hypotension or tissue edema. Evidence to support use of glucocorticosteroids to treat anaphylaxis is lacking, and their use in an emergency department setting does not appear to affect the relapse rate.

Individuals who survive an episode of anaphylaxis can have severe anxiety, including post-traumatic stress disorder, due to the life-threatening nature of the event and its unpredictability. In such cases, appropriate counseling and sometimes even medication may be required (Chapter 362).

PREVENTION

Patients who have experienced an anaphylactic reaction are at greatest risk for another episode. Such individuals should wear a Medic-Alert bracelet; carry an epinephrine autoinjector (e.g., EpiPen or AuviQ) and be instructed in its use; and understand the value of supine positioning when an attack begins.[22] Avoidance of nonspecific β-blockers and ACE inhibitors is recommended, because either may worsen the severity of an anaphylactic episode, and non-specific β-blockers might interfere with epinephrine treatment. In patients who have had recurrent attacks of anaphylaxis, prophylactic use of H_1- and H_2-receptor antihistamines, a leukotriene antagonist, a cyclooxygenase inhibitor, or cyclosporine may be considered under expert guidance. In patients with idiopathic anaphylaxis or mastocytosis (Chapter 235), omalizumab may be useful under expert supervision, but it is currently approved by the FDA only for poorly controlled cases of asthma or chronic urticaria. Glucocorticosteroids do not inhibit mast cell activation in vitro or immediate skin test wheal/flare responses to allergens in vivo, and chronic glucocorticoids

are not recommended except perhaps in selected patients with recurrent anaphylaxis under expert oversight.

Specific anaphylactic syndromes have unique considerations. Insect venom allergy can be treated by venom immunotherapy, which decreases the risk of anaphylaxis after future stings by about 97%.[23] Reactions to radiocontrast media can be prevented or attenuated by administration of intravenous hydrocortisone (200 mg) plus 50 mg of diphenhydramine 1 hour before the procedure, sometimes accompanied by oral cimetidine (300 mg) and ephedrine (25 mg). Patients who are hypersensitive to penicillin should avoid β-lactam antibiotics in general but can be desensitized if an antibiotic in this class is critically needed. Desensitization protocols also have been applied to chemotherapeutics, biologics, and other medications, thereby enabling patients to tolerate needed medications. However, desensitization is temporary; once the drug has cleared, sensitivity is likely to return.[24] Most individuals who have a history of a penicillin or amoxicillin allergy lose their sensitivity, which can be determined by allergy skin testing and oral challenge. For persons diagnosed as penicillin allergic during childhood, the promotion of universal delabeling procedures, such as skin testing and challenges, is recommended.

Autoimmune progesterone-mediated anaphylaxis may respond to medical or surgical interventions that prevent menses and to progesterone desensitization. Perimenstrual anaphylaxis may respond to the luteinizing hormone–releasing hormone analog leuprolide, oophorectomy, or conjugated estrogens.

Patients who have systemic mastocytosis (Chapter 235) should avoid using direct mast cell agonists such as vancomycin and most narcotic agents with the exception of fentanyl. Aspirin-intolerant asthmatic patients who have sinus polyps (Chapter 394) can be desensitized to aspirin and placed on a daily dose to maintain desensitization status, thereby resulting in better control of asthma, shrinkage of polyps, and reduction of hyposmia. Anti-IL-5, anti-IL-5R, or anti-IL-4Rα monoclonal antibody therapy can also control polyps and asthma (Chapter 75).

Legislation requires that foods or ingredients containing a major food allergen be specifically labeled as such. These products, which account for at least 90% of allergic food reactions, include milk, eggs, fish, shellfish, tree nuts, peanuts, wheat, soybean, and sesame. Individuals who have food allergies must practice avoidance of the provocative agent. However, anti-IgE neutralization therapy or oral immunotherapy can sometimes protect against inadvertent exposure to food allergens. Feeding peanuts to children at risk for developing peanut allergic disease prevents the majority of them from becoming allergic. Anti-IgE therapy (i.e., omalizumab) in peanut-allergic individuals can increase the threshold of peanut ingestion needed to cause an allergic reaction and reduce the risk of reactions during oral peanut immunotherapy, but it has not been FDA approved for these indications.[A1] Palforzia is an oral peanut immunotherapy that can increase tolerance to peanuts in children with peanut allergy when used under expert oversight.[A2] Exercise-dependent anaphylaxis sometimes occur within several hours of ingesting any food, regardless of whether sensitivity to the food can be documented, and might be avoided by delaying exercise until several hours after eating.

The only preventive strategy for latex allergy is avoidance. Elimination of latex-powdered gloves and the availability of nonlatex nitrile or polyvinyl gloves are diminishing the prevalence of latex allergy among medical personnel.

PROGNOSIS

Among patients with anaphylaxis seen in emergency departments, mortality is about 0.1%, but it rises to about 1% in patients who require hospitalization. Recurrences are uncommon in the first several days after the original event but are likely to occur with any subsequent exposure to the precipitating agent. Even if no cause is found, prognosis is generally excellent if patients adhere to preventive measures and always carry injectable epinephrine.

DRUG ALLERGY

MARIANA CASTELLS

DEFINITION

About 80% of adverse drug reactions are predictable and dose dependent, whereas about 20% are unpredictable and dose independent (E-Fig. 234-1). These latter reactions include immediate and delayed drug allergies and hypersensitivities (Fig. 234-1).

EPIDEMIOLOGY

Drug allergy has a spectrum of presentations and can be fatal. Any drug can induce allergic and hypersensitivity symptoms in the appropriate context and host. The incidence and prevalence of drug allergy vary between inpatient and outpatient settings. Drug reactions that lead to visits to emergency departments occur in 4 per 1000 individuals and are more frequent in women.

The most common presentation of drug reaction is skin rash, which is observed in 2 to 4% of hospitalized patients. Antibiotics, chemotherapy drugs, monoclonal antibodies, small molecules, antihypertensive agents, contrast media, and antiepileptic agents are among the most frequently implicated (Table 234-1). The incidence of drug reaction among hospitalized patients is about 6%, of which about 40% are severe drug allergy reactions and 1% result in death.

The prevalence of self-reported drug allergy is about 35%, with an average of nearly two drug allergies reported per patient. Penicillin, sulfonamides, opiates, and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most frequently reported drug allergies.[1,2] For example, 20% of the general population worldwide claims to be allergic to penicillin, but further evaluation confirms the allergy in less than 1%.

Risk Factors

The risk for sensitization to a drug depends on its chemical structure, dose, route of administration, and duration of treatment. Women are at greater risk for drug allergies than men, likely related to their immune and genetic background, cyclical exposure to endogenous and exogenous hormones, pregnancy, and exposures to cosmetics and household products. In one study for example, 70% of patients seen in an emergency department for drug-induced anaphylaxis were women. Progestogen hypersensitivity, which is a rare condition associated with allergic symptoms such as dermatitis and anaphylaxis, is observed in women who are exposed to birth control medications, in vitro fertilization, or interrupted menstrual cycles. White patients are more likely to report drug allergies, but allergies to thiazide diuretics, NSAIDs, and angiotensin-converting enzyme inhibitors are more frequent in Black patients, and angiotensin receptor blockers are more frequent in Blacks compared with Whites.

Recurrent exposure to drugs and other chemicals is associated with a higher risk of drug allergy. For example, patients who have cystic fibrosis (Chapter 77) or spina bifida (Chapter 385) and who undergo multiple surgical procedures are susceptible to increased sensitization to IgE and reactions to latex and antibiotics. Patients who have acquired immunodeficiency syndrome (AIDS, Chapter 355) also have a higher rate of drug allergy, especially dermatologic reactions to sulfa medications. The chemical structure of quaternary ammoniums that are present in cosmetics and other products is shared by general anesthetic agents, thereby potentially sensitizing individuals for perioperative anaphylaxis.[3]

Genetics also contribute to the risk of drug allergy. Hereditary α-tryptasemia, which is an autosomal dominant inherited trait due to the duplication of the *TPSAB1* tryptase gene, predisposes to anaphylaxis, including drug-induced anaphylaxis. This condition is present in 4 to 6% of the general population and is associated with blood tryptase levels greater than 9 ng/mL.[4]

The non-IgE mast cell receptor MRGPRX2 is the target of reactions to general anesthetics, quinolones, vancomycin, and positively charged compounds. Reactions mediated by this receptor can occur upon first exposure due to direct activation of mast cells.[5]

Multidrug hypersensitivity refers to patients who react to multiple unrelated medications. Multidrug hypersensitivity is typically associated with delayed skin symptoms, including drug reaction with eosinophilia and systemic symptoms (DRESS) and is thought to be the result of excessive T-cell

DRUG ALLERGY

MARIANA CASTELLS

DEFINITION

About 80% of adverse drug reactions are predictable and dose dependent, whereas about 20% are unpredictable and dose independent (E-Fig. 234-1). These latter reactions include immediate and delayed drug allergies and hypersensitivities (Fig. 234-1).

EPIDEMIOLOGY

Drug allergy has a spectrum of presentations and can be fatal. Any drug can induce allergic and hypersensitivity symptoms in the appropriate context and host. The incidence and prevalence of drug allergy vary between inpatient and outpatient settings. Drug reactions that lead to visits to emergency departments occur in 4 per 1000 individuals and are more frequent in women.

The most common presentation of drug reaction is skin rash, which is observed in 2 to 4% of hospitalized patients. Antibiotics, chemotherapy drugs, monoclonal antibodies, small molecules, antihypertensive agents, contrast media, and antiepileptic agents are among the most frequently implicated (Table 234-1). The incidence of drug reaction among hospitalized patients is about 6%, of which about 40% are severe drug allergy reactions and 1% result in death.

The prevalence of self-reported drug allergy is about 35%, with an average of nearly two drug allergies reported per patient. Penicillin, sulfonamides, opiates, and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most frequently reported drug allergies.[1,2] For example, 20% of the general population worldwide claims to be allergic to penicillin, but further evaluation confirms the allergy in less than 1%.

Risk Factors

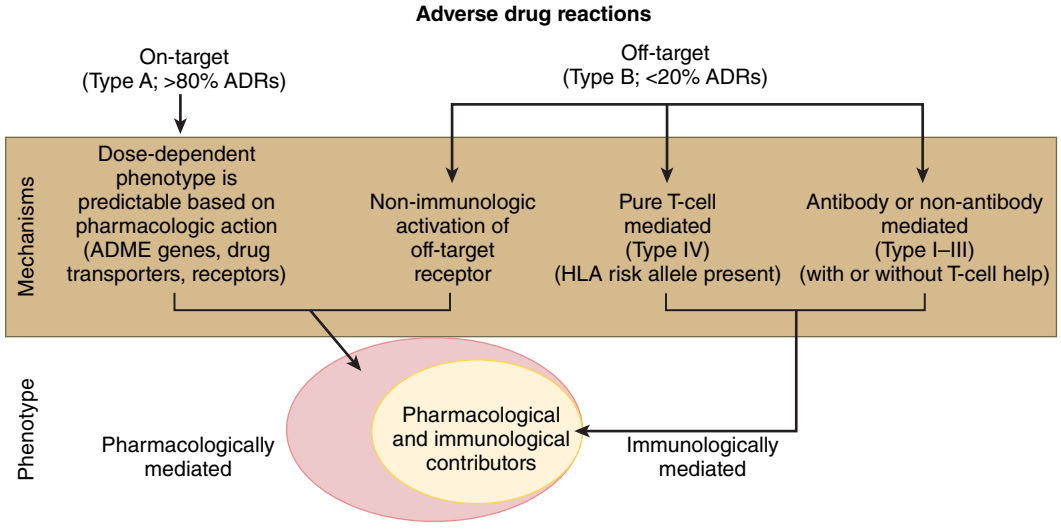
The risk for sensitization to a drug depends on its chemical structure, dose, route of administration, and duration of treatment. Women are at greater risk for drug allergies than men, likely related to their immune and genetic background, cyclical exposure to endogenous and exogenous hormones, pregnancy, and exposures to cosmetics and household products. In one study for example, 70% of patients seen in an emergency department for drug-induced anaphylaxis were women. Progestogen hypersensitivity, which is a rare condition associated with allergic symptoms such as dermatitis and anaphylaxis, is observed in women who are exposed to birth control medications, in vitro fertilization, or interrupted menstrual cycles. White patients are more likely to report drug allergies, but allergies to thiazide diuretics, NSAIDs, and angiotensin-converting enzyme inhibitors are more frequent in Black patients, and angiotensin receptor blockers are more frequent in Blacks compared with Whites.

Recurrent exposure to drugs and other chemicals is associated with a higher risk of drug allergy. For example, patients who have cystic fibrosis (Chapter 77) or spina bifida (Chapter 385) and who undergo multiple surgical procedures are susceptible to increased sensitization to IgE and reactions to latex and antibiotics. Patients who have acquired immunodeficiency syndrome (AIDS, Chapter 355) also have a higher rate of drug allergy, especially dermatologic reactions to sulfa medications. The chemical structure of quaternary ammoniums that are present in cosmetics and other products is shared by general anesthetic agents, thereby potentially sensitizing individuals for perioperative anaphylaxis.[3]

Genetics also contribute to the risk of drug allergy. Hereditary α-tryptasemia, which is an autosomal dominant inherited trait due to the duplication of the *TPSAB1* tryptase gene, predisposes to anaphylaxis, including drug-induced anaphylaxis. This condition is present in 4 to 6% of the general population and is associated with blood tryptase levels greater than 9 ng/mL.[4]

The non-IgE mast cell receptor MRGPRX2 is the target of reactions to general anesthetics, quinolones, vancomycin, and positively charged compounds. Reactions mediated by this receptor can occur upon first exposure due to direct activation of mast cells.[5]

Multidrug hypersensitivity refers to patients who react to multiple unrelated medications. Multidrug hypersensitivity is typically associated with delayed skin symptoms, including drug reaction with eosinophilia and systemic symptoms (DRESS) and is thought to be the result of excessive T-cell



E-FIGURE 234-1. Classification of adverse drug reactions. Hypersensitivity drug reactions include Type A reactions, which are dose dependent and based on the pharmacologic action of the drugs, and Type B reactions, with non-immunologic activation of off-target receptors and immune-mediated reactions (T-cell mediated with HLA alleles risk) and antibody mediated (Type I-III). ADR = adverse drug reactions; ADME = genes involved in absorption, distribution, metabolism, and excretion; HLA = human leukocyte antigen. (White KD, Chung WH, Hung SI, et al. Evolving models of the immunopathogenesis of T cell-mediated drug allergy: the role of host, pathogens, and drug response. *J Allergy Clin Immunol*. 2015;136:219-235.)

ABSTRACT

Drug allergy and hypersensitivity are growing health care concerns that encompass a new discipline led by allergists and clinical immunologists. In the past 25 years, an explosion of new targeted drugs, such as monoclonal antibodies and small molecules, have led to an increased risk for allergic drug reactions. Desensitization has become a safe, first-line therapy for patients with drug-induced immediate and delayed allergic reactions.

stimulation with a persistent increase in activated CD4+ T cells that express PD1 and CD28.[6]

PATHOBIOLOGY

Drug allergy can be divided into acute, antibody-mediated, immune complex-mediated, and delayed (T-cell-mediated) reactions. As illustrated by penicillin allergy (E-Fig. 234-2), antibody-mediated reactions include types I, II, and III; T-cell-mediated type IV reactions are divided into IVa to IVd. Drug antigens such as insulin and haptens such as penicillin and carboplatin are bound to carrier proteins and are presented to T-cells by antigen-presenting cells during sensitization, thereby leading to the generation of cytotoxic T-cells and to the production of IgG and IgE antibodies by B-cells. The severity of immediate reactions involving two or more organs is considered anaphylaxis (Table 234-1; Chapter 233). Additional phenotypes of immediate reactions include cytokine release reactions, mixed reactions, and complement-mediated reactions (Fig. 234-2). Interleukin (IL)-6 levels at the time of a reaction are predictive of fever, chills, and oxygen desaturation in cytokine-release reactions and mixed reactions.[7]

Reactions occurring 6 hours or more following drug administration can be due to immunologic and nonimmunologic off-target receptor activation and can affect a single organ or be multisystemic. Specific HLA haplotypes are associated with severe cutaneous reactions and systemic symptoms to drugs such as abacavir, carbamazepine, allopurinol, sulfonamide, and vancomycin.

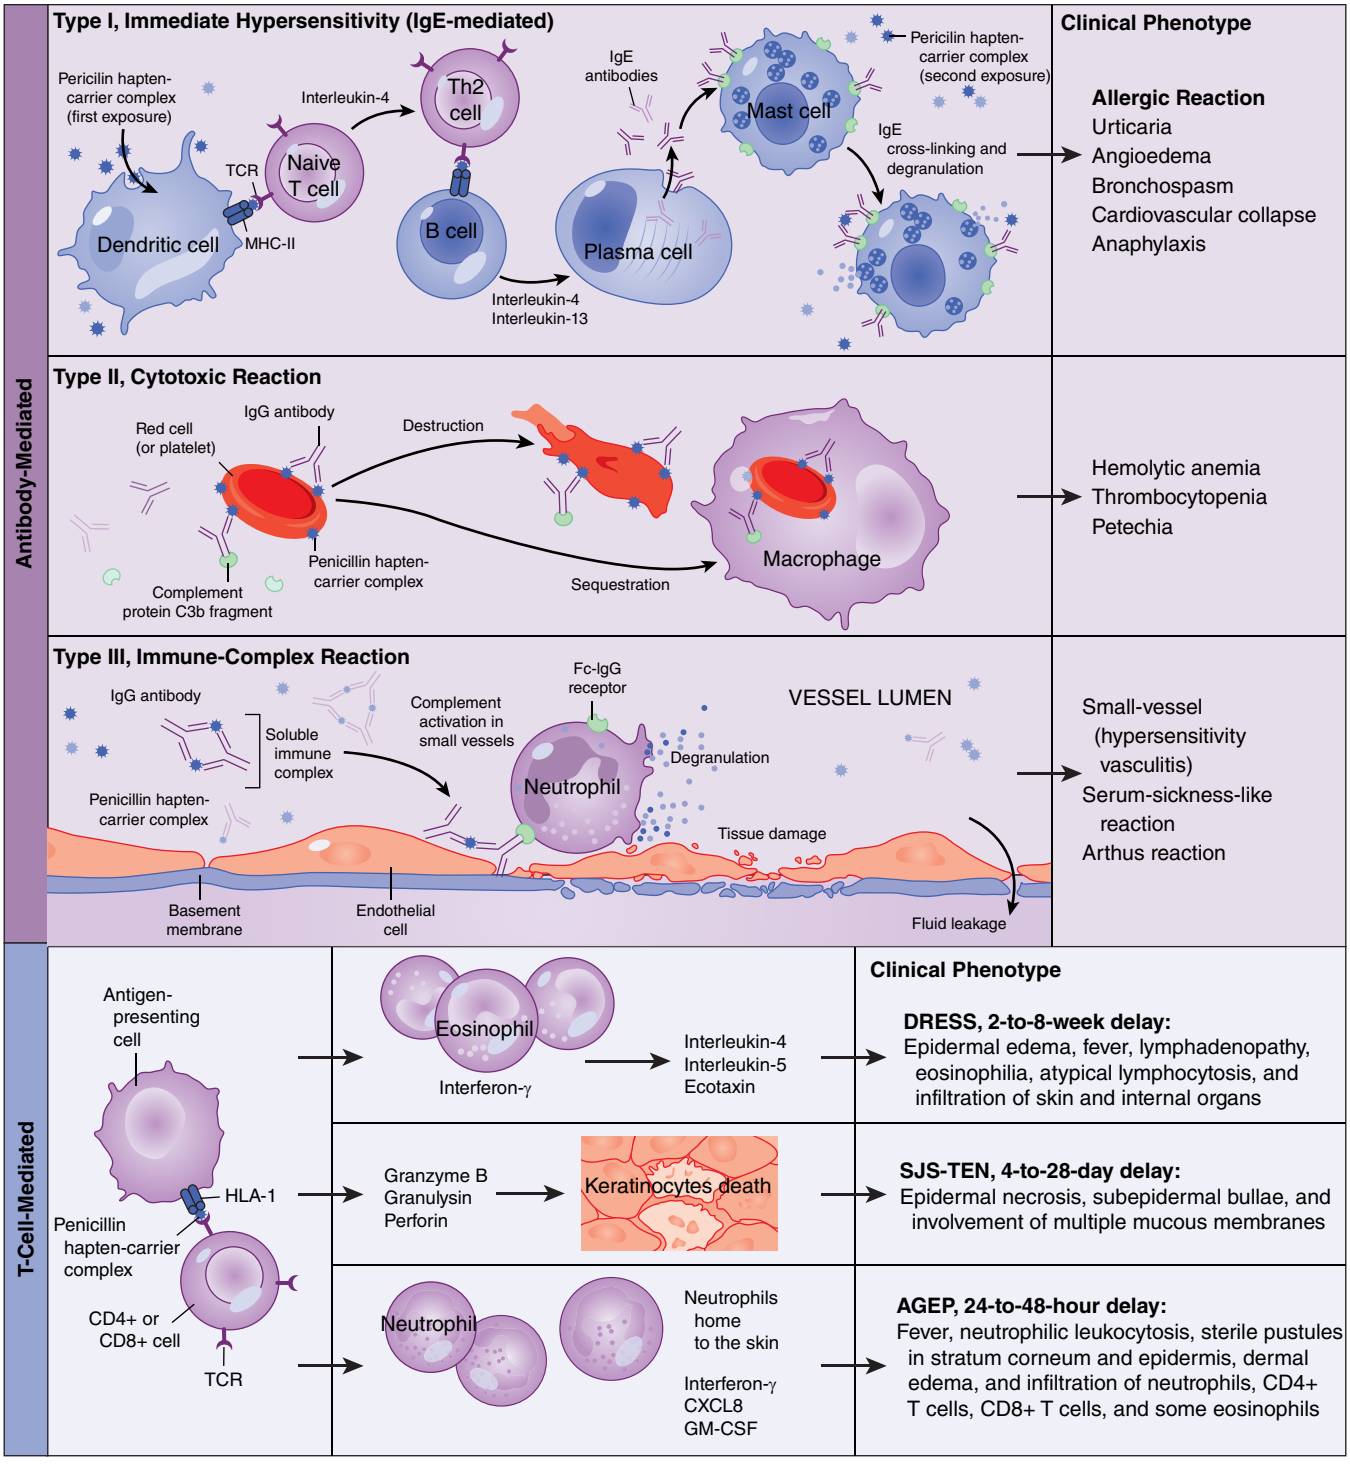
TABLE 234-1 THE BROWN CLASSIFICATION OF THE SEVERITY OF DRUG REACTIONS

GRADE	SEVERITY	# OF ORGAN SYSTEMS INVOLVED	ABNORMAL VITAL SIGNS
1	Mild	1	No
2	Moderate	≥2	No
3	Severe	≥2	Yes*

*One or more of hypotension (systolic blood pressure <90 mm Hg), hypoxia (oxygen saturation <92%), or neurologic compromise (i.e., collapse, altered level of consciousness, or seizures).
Castells M, Khan D, Phillips, E. Penicillin allergy. *N Engl J Med*. 2019;381:2338-2351.

CLINICAL MANIFESTATIONS

The most common manifestation of a drug allergy is a rash, which ranges from mild to potentially life-threatening.[8] The range of dermatologic conditions (Fig. 234-3) include contact dermatitis, fixed drug eruptions, erythema multiforme (Fig. 406-16), and angioedema (Table 234-2).[9] Patients with a drug-specific IgE (Type 1 reaction) will have symptoms that may include pruritus, erythema, angioedema, wheezing, and throat tightness.



E-FIGURE 234-2. Clinical manifestations and mechanisms of adverse reactions to penicillins. Antibody-mediated reactions are Type I reactions involving the activation of mast cells and basophils through IgE and non-IgE mechanisms and the release of inflammatory mediators leading to urticaria and anaphylaxis. Type II cytotoxic reactions are mediated by IgG and complement leading to cell destruction as in hemolytic anemia. Type III reactions result from IgG immune complexes generation, complement activation, and tissue damage as in serum sickness-like reactions. Type IV reactions result from T-cell activation, which can be limited to single organ or present systemic involvement. AGEP = acute generalized exanthematous pustulosis; DRESS = drug reaction with eosinophilia and systemic symptoms; Ig = immunoglobulin; SJS = Stevens-Johnson syndrome; TCR = T-cell receptor; TEN = toxic epidermal necrolysis. (From Castells M, Khan DA, Phillips EJ. Penicillin allergy. *N Engl J Med*. 2019;381:2338-2351.)

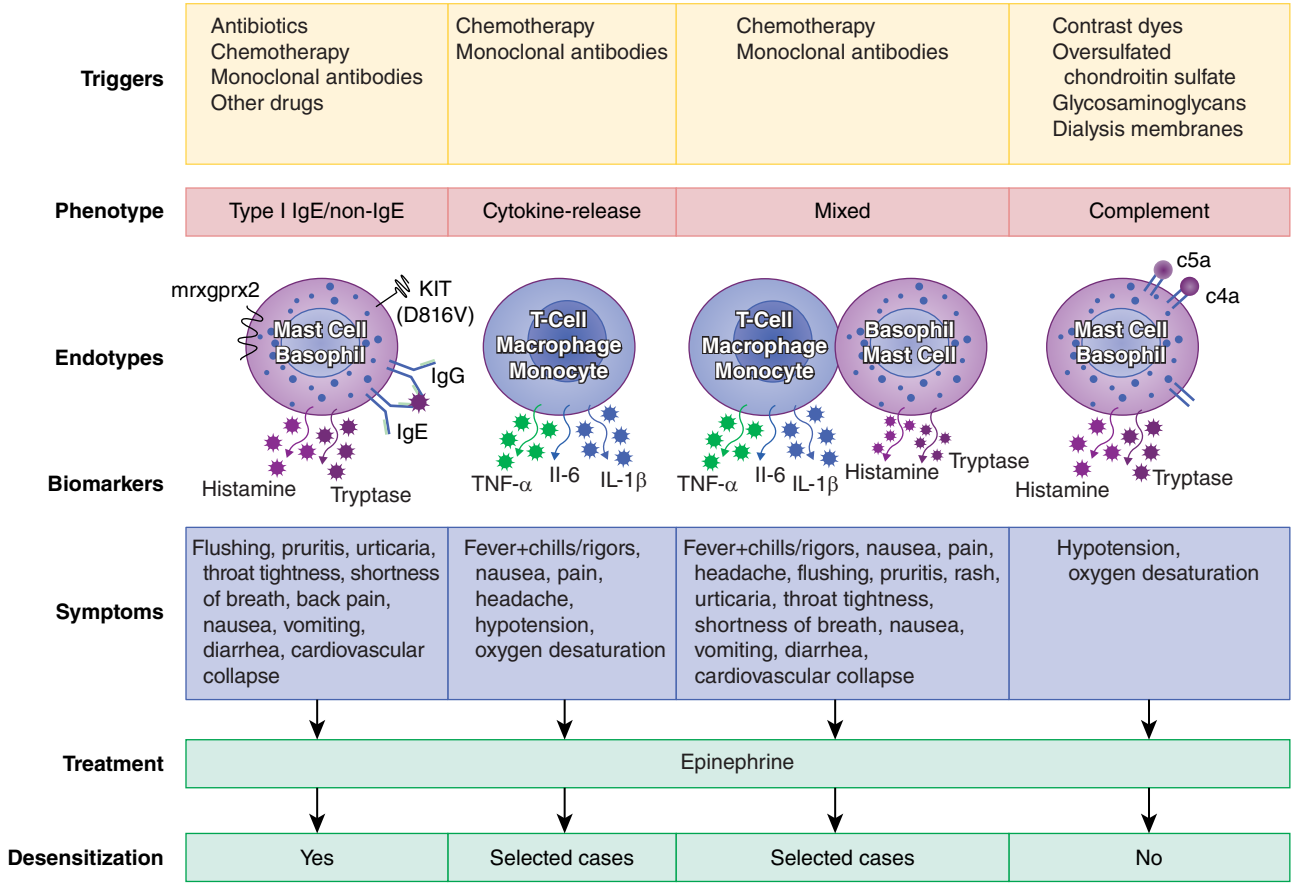


FIGURE 234-2. **Phenotypes of immediate reactions include Type I IgE and non-IgE, cytokine-release CRR, mixed reactions, and complement reactions.** Underlying endotypes and underlying mediators available clinically, such as tryptase and IL-6. Ig = immunoglobulin; IL = interleukin; TNF = tumor necrosis factor. (Adapted from Labella M, Garcia-Neuer M, Castells M. Application of precision medicine to the treatment of anaphylaxis. *Curr Opin Allergy Clin Immunol*. 2018;18:190-197.)

Hepatic Manifestations	Renal Manifestations	Lymphoid Manifestations	Cardiac Manifestations	Neurologic Manifestations	Pulmonary Manifestations	Autoimmune Manifestations	Drug-Induced Immune Cytopenias Manifestations
Cholestasis: aminosalicylic acid, dapsone **Hepatocellular damage:** phenothiazines, erythromycin **Mixed pattern:** halothane, isoniazid, diclofenac, phenytoin, sulfonamides	**Nephrotic syndrome:** gold salts, captopril, NSAIDs, penicillamine **Acute interstitial nephritis:** β-lactams, NSAIDs, sulfonamides	**Pseudolymphoma:** phenytoin, lamotrigine **Infectious mononucleosis-like syndrome:** aminosalicylic acid, dapsone	Sulfonamides β-lactams	**Peripheral neuritis:** colchicine, nitrofurantoin, sulfonamides NSAIDs	**Pulmonary infiltrates with eosinophilia:** minocycline, nitrofurantoin, taxenes **Pneumonitis & fibrosis:** bleomycin, amiodarone **Noncardiogenic pulmonary edema:** hydrochlorothiazide, cocaine, heroin, methadone	**Drug-induced lupus:** hydralazine, procainamide	**Thrombocytopenia:** quinidine, gold salts, sulfonamides, heparin, oxaliplatin **Hemolytic anemia:** penicillin, methyldopa **Agranulocytosis:** sulfonamides, propylthiouracil, quinidine, procainamide, phenytoin

FIGURE 234-3. **Organ and system specific reactions and implicated drugs.** β-lactams = beta-lactams; NSAIDs = nonsteroidal anti-inflammatory drugs. (Adapted from Grammer LC. Drug allergy. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.)

Several clinical entities with extreme clinical presentations must be recognized. Type I reactions (Table 234-3) can result in anaphylaxis (Chapter 233), which can lead to death if not diagnosed and treated promptly. Drug reaction with eosinophilia and systemic symptoms (DRESS; Fig. 407-4)[10] is manifest by extensive skin rash, fever, organ involvement, and lymphocytosis/lymphadenopathy. Both Stevens-Johnson syndrome and toxic epidermal necrolysis (Fig. 407-5) are characterized by extensive skin necrosis and detachment of the epidermis. Drugs can also cause a variety of reactions that are manifested in other organs, including liver reactions (Chapter 136), acute interstitial nephritis (Chapter 108), and pulmonary infiltrates with eosinophilia (Chapter 82).

Reactions to Specific Drugs

Antibiotics

Reactions to antibiotics are reported worldwide, and children are often labeled as having antibiotic allergies when treated with them for viral infections. About 5 to 10% of hospitalized patients demonstrate an allergy to antibiotics, the most common being penicillin, sulfonamides, quinolones, and macrolides.[11]

TABLE 234-2 DRUGS FREQUENTLY IMPLICATED IN ALLERGIC DRUG REACTIONS

Allopurinol
Antibiotics (β-lactams, sulfas, nitrofurans)
Anticonvulsants (hydantoin, phenobarbital, carbamazepine)
Antihypertensive agents (angiotensin-converting enzyme inhibitors)
Antipsychotic tranquilizers
Antisera (antitoxins, antivirals)
Antituberculosis drugs (isoniazid, rifampicin)
Aspirin and nonsteroidal anti-inflammatory drugs
Biologics (monoclonal antibodies such as anti–tumor necrosis factor and other recombinant DNA protein products)
Chemotherapy agents (platins, doxorubicin, taxanes)
Enzymes (L-asparaginase, streptokinase, chymopapain)
Muscle relaxants (rocuronium, succinylcholine)
Opioids
Radiocontrast media
Vaccines (egg protein, gelatin)

From Grammer LC. Drug allergy. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. 26th ed. Philadelphia: Elsevier; 2020.

TABLE 234-3 DRUGS ASSOCIATED WITH ANAPHYLAXIS

DRUG	FREQUENCY	COMMENTS
Aspirin and NSAIDs	About 50%	Mechanism thought to be specific to NSAID; patients can tolerate other COX-1 inhibitors
β-lactam antibiotics	About 15%	Amoxicillin with clavulanic acid is common culprit
Fluoroquinolones	About 9%	
Vancomycin	Rare	Associated with "red man" syndrome and anaphylaxis
Radiocontrast media	0.045% for nonionic contrast agents	Gadolinium is reported to induce anaphylactic events only one-tenth as often as radiocontrast
Proton-pump inhibitors		High cross-reactivity; skin testing can be used to select alternate choices
Neuromuscular blocking agents	Associated with about 50% of perioperative anaphylaxis events	Mortality = 1.4%, suxamethonium, atracurium, and rocuronium are most commonly associated with anaphylaxis
Sugammadex		IgE mechanism
Barbiturates		Direct mast cell histamine release
Opioids		Can induce direct histamine release from mast cells, rarely IgE sensitization. Low potency opioids are the most common triggers; rarely seen with fentanyl
Chlorhexidine		Patients can have IgE sensitization from toothpaste, mouthwash, etc. and develop anaphylaxis during operative procedures
Dyes		For example, methylene blue and isosulfan blue used in cancer-mapping procedures
Colloids	0.05-0.1%	Gelatin and dextran more commonly associated with anaphylaxis compared to albumin and starch
Vaccines	1/1,000,000	COVID-19 vaccines have a higher frequency of anaphylaxis (1/100,000)
Local anesthetics	Rare	

COVID-19 = coronavirus-19 disease; Ig = immunoglobulin; NSAID = nonsteroidal anti-inflammatory drug.

Delayed benign rashes are the most common presentation, and type I reactions and anaphylaxis preclude further use of the medications, unless desensitization provides safe reintroduction. Antigenic determinants of penicillin include the major β-lactam ring that is common to all beta lactams and the side chain R1, which is implicated in cross reactivity with cephalosporins. Use of third-, fourth-, and fifth-generation cephalosporins, aztreonam, and carbapenems are safe in patients who have a history of penicillin allergy.

Sulfonamides are the second-most-common cause of antibiotic allergy, but such allergies do not preclude the use of nonantibiotic sulfonamides. The risk of an allergic reaction to sulfonamide nonantibiotic is lower among patients who have a history of hypersensitivity to sulfonamide antibiotics than among patients who have hypersensitivity to penicillins.

Aspirin and NSAIDS

Aspirin and NSAIDs can induce urticaria and angioedema, and they can exacerbate symptoms in patients with chronic urticaria and angioedema. Delayed reactions to NSAIDs and aspirin include fixed drug eruptions and maculopapular eruptions,[12] and both drugs can also cause anaphylaxis.[13]

Aspirin-exacerbated respiratory disease occurs in 20% of patients who have severe asthma (Chapter 75), especially among women, and is associated with recurrent nasal polyposis (Chapter 394), prior sinus surgery, and lack of sense of smell. COX-1 blockade by aspirin is associated with a decrease in prostaglandin E2 and an increase in leukotriene E4. The ingestion of aspirin and NSAIDs induces severe asthmatic episodes, which are modulated by leukotriene blockers such as montelukast, zafirlukast, and zileuton. Aspirin and NSAIDs have universal cross-reactivity, and aspirin desensitization blocks asthmatic reactions to aspirin and NSAIDs. Patients with aspirin-exacerbated respiratory disease tolerate COX-2 inhibitors.

Cancer Chemotherapy

Most chemotherapy drugs can induce allergic reactions.[14] Such reactions are commonly related to platins and taxanes, with fewer reactions seen with doxorubicin, methotrexate, cyclophosphamide, and gemcitabine. Reactions to carboplatin, cisplatin, and oxaliplatin are classical type I IgE-mediated reactions that require multiple exposures for sensitization. Desensitization is safe and effective for the continuation of first-line therapies, with limited costs and extension of life span. Oxaliplatin can induce mixed and cytokine release reactions and, in rare cases, generate oxaliplatin IgG antibodies that bind to platelets, thereby inducing thrombocytopenia and bleeding and precluding further treatment or desensitization.[15]

Reactions to taxanes can occur with or without IgE sensitization, at first exposure, or after multiple exposures; cross reactivity to environmental allergens and diluents have been implicated. Up to 10% of patients treated with taxanes can present with reactions that range from flushing to severe back and chest pain, with oxygen desaturation and cardiovascular collapse. Diluents such as cremophor and polysorbate can activate complement. IgE sensitization to paclitaxel and docetaxel is less common.

Monoclonal Antibodies

Reactions to monoclonal antibodies, which are more frequent with chimeric and humanized antibodies than with fully human monoclonal antibodies, can occur at first exposure or after repeated exposures.[16] Rituximab, infliximab, tocilizumab, brentuximab, trastuzumab, obinutuzumab, omalizumab, cetuximab, and adalimumab are among the most frequently implicated drugs. Infusion reactions are frequent and can occur with up to 10% of infusions. Type I reactions are responsible for about 65% of cases, mixed reactions for about 20%, cytokine-release reactions in about 10%, and delayed type IV reaction in about 5%.

Perioperative Anaphylaxis

Many commonly used drugs and agents in hospitalized patients are associated with anaphylaxis, especially in the perioperative environment (Table 234-3).[17] Perioperative anaphylaxis[18] is a rare, life-threatening medical emergency that occurs in about 1 per 10,000 anesthetics procedures and is associated with a mortality rate of 4%. Antibiotics such as β-lactams, latex, chlorhexidine, and neuromuscular blocking agents are the most common culprits. Paired blood levels of tryptase, obtained during the event and about 2 weeks later, provide evidence of mast cell activation and help establish the diagnosis.

Vaccines

Vaccines can rarely cause anaphylaxis (Chapter 233), with an estimated overall incidence of 1.3 per million, but the incidence is about 10-fold higher for COVID-19 vaccines.[19] Vaccines also can cause delayed hypersensitivity[20] reactions.

DIAGNOSIS

Diagnosis of drug allergy is largely based on obtaining an accurate clinical history of all drugs taken by the patient, including over-the-counter medications and alternative therapies (Chapter 30). The patient should be questioned

about prior use and past reactions to medications. Drug classes most commonly associated with drug allergies include β-lactam antibiotics, sulfa-containing medications, NSAIDs, and anticonvulsants (see Table 234-2). Unless patients have been previously exposed to the drug, allergic or hypersensitivity drug reactions rarely occur in the first week of continuous therapy. Conversely, a drug that has been used consistently for several months or longer rarely causes an allergic reaction.

For patients with presumed anaphylaxis, an elevated serum tryptase level may be useful to confirm the diagnosis (Chapter 233), although the test must be performed within 30 minutes to 6 hours from initiation of symptoms. Plasma histamine levels are not generally useful owing to their short half-life. Skin testing may be useful in the setting of immediate IgE-mediated drug reactions but should not be performed in the setting of severe reactions or in patients who are at high risk for anaphylaxis.

TREATMENT AND PREVENTION

Recognition of the symptoms of drug allergy in the appropriate clinical setting should lead to prompt discontinuation of the potential offending agents.[21] Patients with presumptive anaphylaxis should be managed with airway and blood pressure support and epinephrine (Chapter 233). Oxygen and inhaled bronchodilators may be required for patients with bronchospasm (Chapter 75). In general, the symptoms of drug allergy will resolve over time with discontinuation of the inciting agent. The mechanisms of drug-induced single organ and multi-system reactions are not well understood and require permanent discontinuation of the medication, since re-exposure can induce faster and more severe reactions.

For patients who develop reactions to monoclonal antibodies, management of anaphylactic reactions requires epinephrine (Chapter 233) and desensitization protocols, which are indicated for first-line treatment. After uneventful desensitization, patients may return to regular infusions. Type I reactions can convert into cytokine release reactions and mixed reaction during desensitization.[22]

Drug Desensitization

Rapid drug desensitization under expert supervision is a safe way to reintroduce essential medications. Desensitization protocols have now been universally adopted for antibiotics, chemotherapy, monoclonal antibodies, small molecules, and all drugs that induce immediate IgE and non-IgE reactions, delayed non-severe cutaneous reactions, and systemic symptoms reactions (Fig. 234-4).[23] Routes of desensitization include intravenous, subcutaneous, intraperitoneal, and intrathecal. Safety is paramount, with no reported deaths after thousands of cases. Although immediate reactions including anaphylaxis can be addressed by rapid desensitization, delayed multiorgan systemic reactions or severe cutaneous adverse reactions with systemic symptoms such as Stevens-Johnson syndrome, toxic epidermal necrolysis, drug reaction with eosinophilia and systemic symptoms (DRESS), and acute generalized exanthematous pustulosis require permanent discontinuation of the drug.

Delabeling Penicillin Allergy

Penicillin allergy is the most common self-reported drug allergy, and 10 to 20% of the world's population engaged in health care claims to be penicillin allergic. After careful evaluation, less than 5% of these allergies are confirmed. Penicillin allergy decays every 10 years, and patients claiming to be allergic 40 years ago are now unlikely to be allergic. Many symptoms listed as an allergy are in fact side effects, such as nausea or headache. Low-risk patients can be directly challenged with penicillin or use other β-lactams without need for testing, while high-risk patients must avoid the drug or be desensitized (E-Fig. 234-3). Formally delabeling penicillin allergy decreases the need for more expensive or less well-tolerated antibiotics, decreases the length of hospitalization, and provides patients with first-line treatments.[24,25] However, resensitization can occur after subsequent exposure, so retesting is often appropriate, especially if the original reaction was severe.[26]

Genotyping for HLA haplotypes and *TPSAB1* genes can identify susceptible individuals and improve safety. For example, screening for the HLA-B57:01 genotype in patients with human immunodeficiency virus infection has successfully eliminated abacavir-induced severe reactions and deaths worldwide. Carbamazepine-induced Stevens-Johnson syndrome is associated with several HLA haplotypes, including the most common HLA-A31*01; genotyping has increased patient safety by preventing re-exposure.

PROGNOSIS

Drug allergy and hypersensitivity can result in considerable morbidity, mortality, and costs. Death rates depend on the clinical presentation, with about 20 deaths per 1 million cases of anaphylaxis to penicillin to over 200,000 per 1 million cases for Stevens-Johnson syndrome and toxic epidermal necrolysis. Drug-related fatalities occur in about 0.1 to 0.5 persons per million population, at an average age of 50 to 55 years.[27] Anaphylaxis, which is the most serious reaction (Chapter 233), has about a 0.1% mortality rate among patients who are seen in emergency departments but usually resolves in 10 to 14 days, although more severe reactions may resolve more slowly. Management of drug allergy with desensitization allows for safe treatment with first-line therapies and improved life expectancy and quality of life (Fig. 234-4).

ABSTRACT

Mastocytosis is a heterogeneous group of disorders that are characterized by pathologic mast cell accumulation in tissues, including skin and bone marrow. The current World Health Organization (WHO) classification of mastocytosis divides the disorders into two broad categories: cutaneous mastocytosis (in which abnormal mast cell infiltration is limited to skin) and systemic mastocytosis (in which other organs are involved, with or without cutaneous mastocytosis). The systemic mastocytoses range from good to very poor prognosis disorders, including indolent systemic mastocytosis, bone marrow mastocytosis, smoldering systemic mastocytosis, systemic mastocytosis with associated hematologic non–mast cell lineage neoplasm, aggressive systemic mastocytosis, and mast cell leukemia. Clinical manifestations may be caused by mediators that are released by activated mast cells as well as by tissue infiltration. These mediators include vasoactive substances (e.g., histamine, prostaglandin D2, and cysteinyl leukotrienes), proteases, and cytokines. Treatment for the less aggressive forms of systemic mastocytosis is largely symptomatic, whereas the more aggressive forms now can be treated with targeted therapies that block the primary driver *KIT* D816V mutation.

KEYWORDS

mastocytosis
KIT
anaphylaxis
mast cells
urticaria pigmentosa
mast cell activation

systemic mastocytosis describes the disorder when it involves internal organs (most commonly the bone marrow) with or without skin disease. In addition, mast cell sarcoma is a rare invasive tumor.

EPIDEMIOLOGY

Mastocytosis can be diagnosed at any age,[2] and the disease has been diagnosed in all ethnic populations. The disease is sporadic, although rare cases of familial occurrence have been described.

Estimates of the prevalence of cutaneous mastocytosis range from 1 in 500 to 1 in 8000 among patients who present to dermatology practices. The prevalence of systemic mastocytosis is estimated to be around 1 in 10,000. However, systemic mastocytosis is likely to be underdiagnosed, since neither findings on physical examination nor routine hematologic or chemistry laboratory abnormalities are specifically associated with the disease.

PATHOBIOLOGY

The pathogenesis of mastocytosis involves the accumulation of clonally expanded mast cells in tissues, where activated mast cells release mediators. The primary reason for the increased numbers of mast cells in tissues appears to be defective apoptosis rather than increased mitotic activity, and the microenvironment and altered chemotaxis may also contribute to the accumulation of mast cells.

Genetics

Mast cells are derived from hematopoietic progenitors (Chapter 137). Systemic mastocytosis is associated with somatic gain-of-function point mutations in the *KIT* (formerly *c-kit*) gene of the mast cell progenitor, thereby leading to a clonal neoplastic expansion of mast cells. *KIT* encodes a transmembrane receptor (Kit) whose intracellular portion functions as a tyrosine kinase enzyme. The extracellular portion of Kit binds the cytokine stem cell factor. The interaction between the stem cell factor and Kit provides the single most important growth and differentiation stimulus for mast cells from their progenitors. Under physiologic conditions, homodimeric stem cell factor binds and cross-links two Kit receptor molecules, thereby leading to autophosphorylation of the tyrosine amino acids of the intracellular portion of the Kit molecule. Phosphorylated tyrosine residues in turn act as docking sites for downstream adaptor and signal transduction molecules that regulate the differentiation, proliferation, chemotaxis, and functional activation of mast cells.

The most common mutation in mastocytosis involves codon 816 in *KIT* (located in exon 17), where replacement of an aspartic acid by a valine residue (D816V) in the Kit protein leads to ligand-independent autophosphorylation.[3] This D816V mutation is present in the skin or bone marrow tissue of more than 90% of adults and approximately 40% of pediatric patients with mastocytosis. Another 40% of pediatric patients carry *KIT* mutations in other exons, most commonly in exons 8 and 9. *KIT* mutations can be demonstrated in non–mast cell hematopoietic lineages in advanced variants of systemic mastocytosis, similar to the multilineage involvement observed in myeloproliferative neoplasms (Chapter 152). The sensitivity of detecting the mutation is much higher when a lesional tissue such as bone marrow or skin is analyzed compared with peripheral blood and when a sensitive technique such as allele specific polymerase chain reaction (PCR) testing is used.

Other pathogenetic factors also appear to be responsible for the final disease phenotype because the presence of the D816V *KIT* mutation alone does not explain the remarkable heterogeneity in the clinical presentation and prognosis of the disease. Molecular aberrations in *TET2*, *SRSF2*, *ASXL1*, *CBL*, *RUNX1*, and *DNMT3A* are the most frequently identified other mutations in advanced forms of systemic mastocytosis. In advanced systemic mastocytosis, most patients carry three or more mutations.

Mast cells are rich sources of cytokines. Activation of mast cells[4] results in the release of various preformed mediators that are stored in mast cell granules, *de novo* synthesis of sulfidopeptide leukotrienes such as leukotriene C_4 and prostaglandins (mostly prostaglandin D_2) from membrane lipids, and synthesis of cytokines. Preformed mediators stored in mast cell granules include histamine; proteases such as tryptase, chymase, and carboxypeptidase A; and proteoglycans such as heparin and chondroitin sulfate.

Mature tryptase enzyme is a serine protease that is stored in mast cell granules and is transiently elevated in serum or plasma after mast cell degranulation episodes, such as anaphylaxis. In contrast, tryptase precursor proenzymes (α and ß protryptases) are constitutively secreted outside the cell, and their serum levels at baseline correlate with mast cell burden.

CLINICAL MANIFESTATIONS

Symptoms

Mastocytosis is a disease with protean clinical manifestations. In general, patients with mastocytosis belong to one of two broad categories: patients who have cutaneous disease alone, and patients who have systemic disease with or without skin involvement. Although some patients may complain only about the cosmetic appearance of urticaria pigmentosa lesions (Fig. 235-1), other patients suffer from frequent episodes of vascular instability or have life-threatening hematologic disease.

The symptoms of mastocytosis are primarily related to the release of vasoactive mast cell mediators (e.g., histamine, leukotriene C_4, and prostaglandin D_2), which cause vasodilation that may lead to flushing, tachycardia, hypotension, presyncope, and syncope. Histamine also causes pruritus and stimulates gastric acid hypersecretion from parietal cells. Elevated serum levels of tumor necrosis factor-α and interleukin-6 may contribute to the fatigue and accelerated osteoporosis that are observed in some patients. In rare aggressive forms of mastocytosis, mast cells may extensively infiltrate into tissues such as the gastrointestinal tract, where they may result in malabsorption, and the liver, where they may cause portal fibrosis with associated portal hypertension.

Activation of mast cells and their release of mediators may occur after triggers, such as temperature changes (e.g., hot showers), exercise, ingestion of alcohol or spicy foods, emotional stress, insect stings, and exposure to certain drugs (e.g., opioid analgesics, nonsteroidal anti-inflammatory drugs, or muscle relaxants). Sometimes, however, activation occurs spontaneously without an obvious trigger. The prevalence of atopic disease in patients with mastocytosis is similar to that in the general population, but patients with anaphylactic sensitivity to Hymenoptera venoms appear to have a disproportionately high prevalence of mastocytosis.

Cutaneous Manifestations

Maculopapular skin lesions of urticaria pigmentosa (known as maculopapular cutaneous mastocytosis) are the most common presentation of cutaneous mastocytosis (Fig. 235-1). These lesions are also present in 50 to 90% of patients with systemic mastocytosis. Remarkably different in appearance from urticaria or hives (Chapter 232), lesions of urticaria pigmentosa are fixed, tan- to salmon-colored lesions that vary in size from a few millimeters to a few centimeters. Lesions are most prominently observed on the trunk and extremities and tend to spare the face and sun-exposed areas of the skin, although facial and scalp involvement may be seen in children. Blistering of the lesions may occur in children, mostly in the first 3 years of life. The lesions are generally not initially pruritic but may urticate after exposure to a number of triggers. Many patients note that the skin lesions become more prominent after exposure to heat or after physical irritation such as rubbing. A localized wheal-and-flare reaction limited to the lesional skin within a few minutes after rubbing or scratching it is known as the Darier sign. The lesions may be concentrated in skin areas that are prone to irritation, such as the axillae and groin. Patients with cutaneous mastocytosis may also manifest other symptoms such as abdominal pain, diarrhea, and flushing.

Uncommon presentations of cutaneous mastocytosis include mastocytomas and diffuse cutaneous mastocytosis. Mastocytomas are benign and generally solitary mast cell tumors, but they can sometimes precede urticaria pigmentosa. Mastocytomas occur almost exclusively in children, and physical irritation of the lesion may result in generalized flushing and other symptoms caused by the release of mediators from their mast cells. Diffuse cutaneous mastocytosis

FIGURE 235-1. Urticaria pigmentosa.

is also seen exclusively in children and is characterized by diffuse thickening of the skin and appendages with a peau d'orange appearance without individual urticaria pigmentosa lesions.

Telangiectasia macularis eruptiva perstans is a rare form of cutaneous mastocytosis that is characterized by diffuse telangiectatic macules. Because the lesions of telangiectasia macularis eruptiva perstans are generally seen in the presence of urticaria pigmentosa, it is uncertain whether telangiectasia macularis eruptiva perstans represents a distinct form of cutaneous mastocytosis.

Systemic Manifestations

Degranulation of mast cells can cause brief, recurrent, and self-limited multiorgan manifestations or recurrent complaints with a prolonged time course. A typical mast cell degranulation episode may variably involve flushing, conjunctival hyperemia, nausea, vomiting, abdominal cramping, diarrhea, tachycardia, and lightheadedness. These symptoms of mast cell activation may occur when mast cells are activated as a reaction to stimuli generated by another pathologic process, but a consistent trigger can be identified in only a small number of patients. Angioedema, hives, and wheezing are uncommon in mastocytosis. Flushing usually involves the face and upper chest area. The episodes usually persist for 30 minutes to a few hours. Hypotension may develop, and the episode can progress to full loss of consciousness. Hypotensive episodes can be life-threatening, particularly in the presence of comorbid conditions, such as cardiac or pulmonary disease.

Gastrointestinal Symptoms

Gastrointestinal symptoms are observed in more than 50% of patients with mastocytosis. Epigastric pain, lower abdominal cramping, nausea, vomiting, or diarrhea can occur episodically in the context of an acute mast cell degranulation episode or on a chronic basis. Gastric acid hypersecretion induced by mast cell–derived histamine may lead to esophagitis, gastritis, and peptic ulcer disease. Diarrhea alternating with constipation may be seen. Severe persistent diarrhea may be complicated by clinically significant malabsorption in patients with aggressive systemic mastocytosis. Hematochezia, hematemesis, and melena are uncommon symptoms that should prompt endoscopic evaluation to exclude coexisting disease. Mild to moderate hepatomegaly with or without elevated aminotransferase levels may be observed, but portal hypertension and ascites are rare and indicate the presence of advanced mastocytosis. Jaundice and cholangiographic findings that resemble primary sclerosing cholangitis (Chapter 141) can occur.

Musculoskeletal Symptoms

Musculoskeletal pain is common and usually resembles fibromyalgia (Chapter 253). Accelerated osteoporosis (Chapter 225) may be seen in a subgroup of patients, particularly patients who have other risk factors, such as postmenopausal women and patients who are receiving glucocorticoid therapy. Pathologic compression fractures and other fragility fractures due to bone involvement may be the initial finding in some patients.[5]

Hematologic Manifestations

Peripheral blood abnormalities are noted in up to 50% of patients with systemic mastocytosis. Mild normochromic normocytic anemia is the most common abnormality, followed by thrombocytopenia, eosinophilia, monocytosis, and leukopenia. Eosinophilia in mastocytosis rarely causes the organ damage that is observed in chronic eosinophilic leukemia or idiopathic hypereosinophilic syndrome (Chapter 156).

Approximately 20% of patients with systemic mastocytosis have evidence of another clonal non–mast cell hematologic disease. These conditions are commonly myeloid (e.g., myeloproliferative neoplasms, myelodysplastic syndromes, or myeloid leukemias) but may also include lymphoproliferative disorders such as lymphomas, myelomas, and lymphocytic leukemias.

DIAGNOSIS

Cutaneous mastocytosis (i.e., disease limited to the skin in the absence of internal organ involvement) is commonly diagnosed in children within the first year of life, whereas systemic mastocytosis is mostly diagnosed in adults by a bone marrow aspiration and biopsy. Many patients have symptoms for several years before mastocytosis is diagnosed. Mastocytosis should be considered in all patients with recurrent anaphylaxis (Chapter 233), especially patients who present with hypotension. The finding of urticaria pigmentosa in adults should always prompt consideration of possible systemic mastocytosis.

The approach to the diagnosis of mastocytosis and its classification can be facilitated by using a systematic approach (Fig. 235-2).

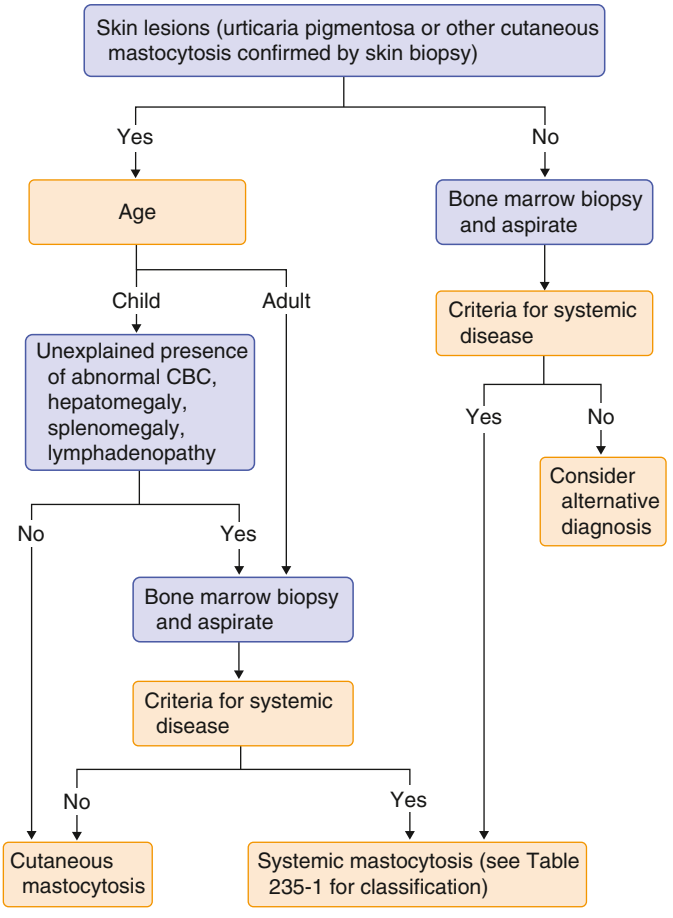

FIGURE 235-2. Suggested diagnostic algorithm for mastocytosis. CBC = complete blood count.

Cutaneous Mastocytosis

The diagnosis of cutaneous mastocytosis is established by observing the typical hyperpigmented maculopapular lesions of urticaria pigmentosa, which should always prompt consideration of mastocytosis, associated with a skin biopsy that shows infiltration of mast cells in the upper dermis, particularly in perivascular locations. Mild increases in the numbers of mast cells can be observed in other inflammatory and neoplastic skin diseases and do not establish a diagnosis of cutaneous mastocytosis without the characteristic skin lesions.

Systemic Mastocytosis

Systemic mastocytosis should be suspected in all patients who have systemic reactions to Hymenoptera stings, especially patients who develop hypotensive near-syncope or syncope. Serum levels of tryptase also may be elevated above the patient's baseline level (to be checked about 2 weeks later) if measured within 4 hours after the onset of the episode, but similar elevations can be seen in patients with mast cell degranulation or anaphylaxis, regardless of the cause.

The median baseline serum tryptase level in a healthy population is approximately 5 ng/mL, and a serum tryptase level higher than 20 ng/mL raises suspicion for systemic mastocytosis in the appropriate clinical setting. A normal tryptase level does not exclude a diagnosis of mastocytosis, and increased tryptase levels can be seen in other conditions, such as hereditary α-tryptasemia (which is seen in up to 7% of the general population), myelodysplastic syndromes, acute myeloid leukemias, chronic eosinophilic leukemia, and chronic renal insufficiency. Metabolites of histamine, such as *N*-methylhistamine, and prostaglandin D_2 can be elevated in a 24-hour urine specimen but are neither more sensitive nor more specific than the baseline serum tryptase measurement in mastocytosis.

Biopsy

The recommended diagnostic procedure to diagnose systemic disease is a bone marrow aspiration and biopsy.[6] This procedure is recommended for all patients with adult-onset urticaria pigmentosa, patients with recurrent symptoms suggestive of mast cell degranulation (such as flushing and hypotension accompanied by abdominal complaints), patients with unexplained

osteoporosis, and patients with suspected hematologic disease. Children who have late-onset skin lesions (especially uniform morphology as opposed to polymorphic lesions of various sizes) and who have persistent maculopapular cutaneous mastocytosis into adulthood should also be considered for diagnostic bone marrow evaluation.

Bone marrow mast cells in systemic mastocytosis often display atypical morphology, such as an elongated (i.e., spindle) shape, hypogranularity, and an eccentric or lobulated nucleus (Fig. 235-3B). These atypical mast cells are usually observed in close association with bone marrow spicules in the aspirate smear. Mast cells in mast cell leukemia may be very sparsely granulated. On flow cytometry, the characteristic finding of systemic mastocytosis is the aberrant expression of CD25, CD2, and/or CD30 on CD117-positive mast cells. Aberrant marker expression can also be demonstrated by immunohistochemical staining of bone marrow biopsy specimens. Bone marrow biopsy and aspirate specimens should be carefully evaluated for the presence of other hematologic disease in every patient with newly diagnosed systemic mastocytosis.

Diagnostic Criteria

The major diagnostic criterion is the presence of multifocal, dense aggregates of 15 or more mast cells in bone marrow or other extracutaneous tissue biopsy sections (see Table 235-2).[7] The mean percentage of mast cells in a healthy bone marrow aspirate is approximately 0.02%, and the percentage does not exceed 1% in most patients with mastocytosis. This major criterion plus at least one minor criterion or the presence of three or more minor criteria in the absence of the major criterion establishes the diagnosis of systemic mastocytosis and distinguishes it from reactive mast cell hyperplasia (Table 235-2). Such clusters are frequently observed around blood vessels and next to bone trabeculae in bone marrow biopsy sections by immunohistochemical staining for tryptase and CD117.

Demonstration of a codon 816 *KIT* mutation (D816V) (or another rarer gain of function mutation in KIT) may be necessary to fulfill the diagnostic criteria in patients who lack the major criterion.[8,9] Examination of lesional tissues, such as skin and bone marrow, affords the highest sensitivity. Codon 816 *KIT* mutations can also be detected in a variety of other neoplastic diseases, such as core binding factor acute myeloid leukemias, sinonasal lymphomas, and seminomas, in addition to mastocytosis. Chronic eosinophilic leukemia is commonly associated with the *FIP1L1-PDGFRA* fusion gene, whereas systemic mastocytosis is associated with codon 816 point mutations of the *KIT* gene.

A rare histologic variant with clustering of mature round mast cells without CD25 expression termed well-differentiated systemic mastocytosis has been described. These patients generally have a history of childhood-onset mastocytosis without the D816V *KIT* mutation and therefore may respond to imatinib as opposed to those with typical systemic mastocytosis carrying the D816V mutation (see Treatment).

A bone densitometry measurement should be recommended as part of the standard evaluation in all patients with systemic mastocytosis. Radiographic abnormalities are seen in up to 75% of patients with mastocytosis; in addition to generalized osteoporosis, bone surveys may show a mixture of sclerotic or lytic lesions, and skeletal scintigraphy may reveal focal or diffuse radiotracer uptake.

Mast cells also may be increased in inflammatory states that affect the gastrointestinal tract. However, quantitation of mast cell numbers in gastrointestinal biopsy specimens is generally not helpful, and the diagnosis of mast cell disease by a gastrointestinal biopsy based solely on increased mast cell numbers without evidence for other criteria should be avoided.

Disease Categories

Each patient diagnosed with mastocytosis should be assigned a disease category (see Table 235-1).[10] *Cutaneous mastocytosis* in the absence of bone marrow and internal organ involvement is the most common category in patients with pediatric-onset disease.

Systemic mastocytosis is divided into the categories of indolent systemic mastocytosis (which is the most common category in adults), bone marrow mastocytosis, smoldering systemic mastocytosis, systemic mastocytosis with an associated hematologic neoplasm, aggressive systemic mastocytosis, and mast cell leukemia (Fig. 235-4). Systemic mastocytosis with an associated hematologic neoplasm, aggressive systemic mastocytosis, and mast cell leukemia are sometimes referred to as advanced systemic mastocytosis, whereas indolent systemic mastocytosis, bone marrow mastocytosis, and smoldering systemic mastocytosis are considered nonadvanced systemic mastocytosis. In adults, indolent systemic mastocytosis is the most common category, and systemic mastocytosis with an associated hematologic neoplasm is the second most common category.

Smoldering systemic mastocytosis denotes patients who have a high burden of mast cells, as evidenced by two or more of the following so called B-findings: more than 30% infiltration by mast cells in bone marrow biopsy and tryptase greater than 200 ng/mL; signs of dysplasia or myeloproliferation without meeting the criteria for an associated hematologic neoplasm; hepatomegaly or splenomegaly without liver dysfunction or hypersplenism; D816V variant allele fraction of 10% or more without C findings or mast cell leukemia. Bone marrow mastocytosis is

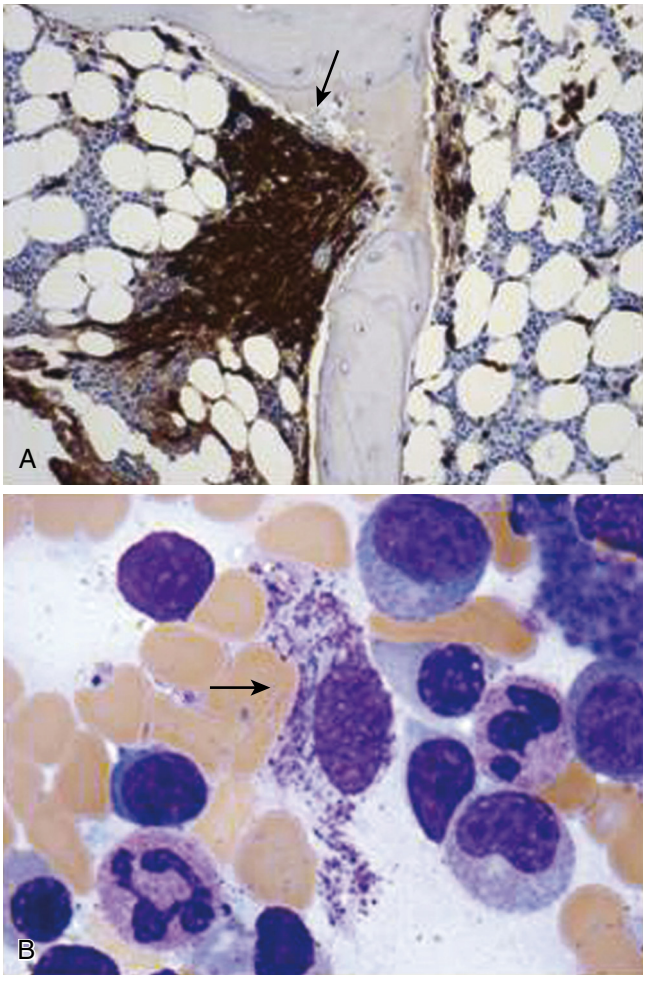

FIGURE 235-3. Diagnostic findings in the bone marrow biopsy specimen and aspirate smear. A, Characteristic mast cell aggregates on tryptase staining (major criterion) in biopsy section (*arrow*). **B,** Mast cells with atypical spindle shapes in aspirate smear (*arrow*).

TABLE 235-2 WORLD HEALTH ORGANIZATION DIAGNOSTIC CRITERIA FOR SYSTEMIC MASTOCYTOSIS

MAJOR
Multifocal, dense infiltrates of mast cells consisting of 15 or more mast cells in aggregates detected in sections of bone marrow and/or other extracutaneous organs, confirmed by tryptase immunohistochemistry or other special stains
MINOR
a. More than 25% of mast cells in the infiltrate in biopsy sections or bone marrow aspirate smears showing spindle shape or atypical morphology
b. Detection of a *KIT*-activating mutation in codon 816 or another critical region of KIT in bone marrow, blood, or other extracutaneous organs
c. Expression of one or more of the aberrant surface markers, CD25, CD2, and/or CD30, by mast cells in bone marrow, blood, or extracutaneous organs
d. Persistent elevation of serum total tryptase >20 ng/mL*

*Criterion not valid if the patient has an associated clonal myeloid disorder. In patients who have known hereditary α tryptasemia, the tryptase level should be adjusted; one method is to divide the total tryptase level by 1+ number of extra α tryptase encoding *TPSAB1* alleles.

Diagnosis requires at least one major plus one minor *or* three minor criteria.

ASM = aggressive systemic mastocytosis; BMM = bone marrow mastocytosis; ISM = indolent systemic mastocytosis; MDS = myelodysplastic syndromes; MPN = myeloproliferative neoplasms; SM-AHN = systemic mastocytosis with associated clonal hematologic non–mast cell lineage disease; SSM = systemic smoldering mastocytosis.

defined by a tryptase level less than 125 ng/mL and the absence of skin lesions, of B- and C-findings, and of features of advanced disease.

Aggressive systemic mastocytosis is a rare category characterized by the presence of organ dysfunction resulting from destructive mast cell infiltration. Aggressive systemic mastocytosis includes systemic findings (so-called C findings) that may involve the hematopoietic, gastrointestinal, and skeletal systems in the form of cytopenias (neutrophils <1000/μL, hemoglobin <10 g/dL or platelets <100,000/μL), palpable splenomegaly with hypersplenism, malabsorption with hypoalbuminemia with or without weight loss, hepatomegaly with portal hypertension and ascites, and large osteolytic lesions (≥2 cm in diameter) with pathologic fractures.

Mast cell leukemia is characterized by 10% or more mast cells in the peripheral circulation or 20% or more mast cells in bone marrow aspirate smears, or both. To diagnose mast cell leukemia, the percentage of mast cells in bone marrow aspirate smears should be assessed in an area of the slide that is sufficiently distant from the spicules. *Mast cell sarcoma* is a rare diagnosis characterized by malignant and invasive solid mast cell tumor.

A subset of patients who have recurrent idiopathic or Hymenoptera venom–induced anaphylaxis also have evidence of clonal mast cells carrying the D816V *KIT* mutation or aberrantly expressing surface CD25, without fully meeting the diagnostic criteria and without displaying urticaria pigmentosa skin lesions. Such patients are provisionally referred to as having a monoclonal mast cell activation syndrome.

TREATMENT

The major goal of treatment for all categories of mastocytosis is to control symptoms, although symptomatic treatment does not change the natural course of the disease. For disease categories with a poor prognosis (i.e., systemic mastocytosis with associated clonal hematologic non–mast cell lineage disease, aggressive systemic mastocytosis, mast cell leukemia, and mast cell sarcoma) or disabling symptoms not controllable by symptomatic management,[11] therapy may be targeted at reducing the number of mast cells.[12]

Medical Therapy

Symptomatic Treatment

Adults with cutaneous and indolent systemic mastocytosis are treated symptomatically. Pruritus in adults usually responds to scheduled doses of histamine$_1$-receptor blocker antihistamines, such as loratadine (10 mg daily), fexofenadine (180 mg with water daily), or cetirizine (5 to 10 mg daily). These doses may be doubled to twice daily if needed. Sedating antihistamines, such as hydroxyzine (25 mg three times daily) or diphenhydramine, may be used before bedtime.

Photochemotherapy (oral psoralen plus ultraviolet A) or phototherapy results in symptomatic improvement and temporary fading of the pigmented skin lesions in up to 50% of patients who have refractory pruritis. The side effects of phototherapy, including increased risk of skin cancer, should be considered.

Histamine$_2$-receptor blocker antihistamines, such as famotidine (20 mg once or twice daily), are usually prescribed as a first-line treatment for patients with gastrointestinal complaints, such as heartburn, nausea, and abdominal pain. Proton pump inhibitors (see Table 124-1) may be added in patients whose abdominal symptoms are refractory to histamine$_2$-receptor blockers. The dual H$_1$- and serotonin-receptor antagonist cyproheptadine (4 mg three times daily) may be used for diarrhea, flushing, or headaches. Oral cromolyn sodium (adult dose, 200 mg four times daily) can reduce abdominal pain, diarrhea, nausea, vomiting, and pruritus, but its benefits vary among patients. Low to moderate doses of systemic glucocorticoids can be beneficial in unusual cases of aggressive mastocytosis that present with recalcitrant diarrhea associated with malabsorption or with hepatomegaly and ascites. Montelukast (10 mg daily) or zileuton may be useful for pruritis or abdominal pain when used in conjunction with H$_1$- and H$_2$-receptor antagonists, but patients should be warned about psychiatric side effects. Masitinib, which is a KIT and LYN kinase inhibitor, has been used to treat severely symptomatic indolent or smoldering systemic mastocytosis under expert oversight.[A1] However, it is not FDA-approved, and fewer than 20% of patients have a 75% or greater improvement from baseline.

Self-administered epinephrine should be considered for all patients even if they do not have any history of anaphylactic episodes, hypotensive episodes, presyncope, or syncope. These episodes should be treated as systemic anaphylaxis (Chapter 233). Omalizumab (a humanized anti-IgE monoclonal antibody) has reduced recurrent anaphylactic or mast cell activation symptoms in case reports, but it is not FDA-approved for this indication.

Cytoreductive Therapies

Cytoreductive therapy is generally considered for advanced disease variants associated with a poor prognosis. Some patients with recurrent life-threatening episodes of mast cell mediator release unresponsive to conventional therapy may also be candidates for cytoreductive therapy after careful consideration of risks and benefits.

Tyrosine kinase inhibitors are considered first-line therapy owing to their efficacy, tolerability, and low rate of adverse effects.[13] Avapritinib is a selective D816V KIT inhibitor that can provide clinical and molecular remission in up to 75% of patients who have advanced mastocytosis with the *KIT* D816V mutation.[14] Avapritinib is approved by the U.S. Food and Drug Administration for advanced disease and is investigational for indolent systemic mastocytosis at the time of this writing. Avapritinib is contraindicated in patients whose platelet counts are less than 50,000/μL because of an increased risk of intracranial bleeding.

Midostaurin (100 mg twice daily), which is a multikinase inhibitor whose targets include the common *KIT* D816V driver mutation, provides a 17% overall response rate in patients with advanced systemic mastocytosis, including mast cell leukemia.[15] Nausea and vomiting are its common adverse effects. Bezuclastinib and elenestinib are other tyrosine kinase inhibitors that are in clinical trials for systemic mastocytosis.

Interferon alfa-2b (0.5 to 5 million units, three to five times per week), alone or with prednisone, can partially improve clinical and laboratory abnormalities in approximately 50% of patients with aggressive systemic mastocytosis, patients with osteoporosis and pathologic fractures, and patients with recalcitrant recurrent anaphylaxis, although complete histopathologic and molecular remissions are rare. Interferon alfa is difficult to tolerate because of its many side effects, including influenza-like symptoms, bone pain, and depression.

Cladribine (a synthetic purine analog given as 0.14 mg/kg in an infusion or subcutaneously on days 1 to 5 and repeated at 4 to 12 weeks until one to nine courses) provides a 22% response rate for indolent and aggressive mastocytosis. However, it is associated with a high risk for lymphopenia, neutropenia, and opportunistic infections.

Ancillary and Other Therapies

Avoidance of the triggers of mast cell degranulation is an important adjunct to the pharmacologic treatment of symptoms. General anesthesia and surgery impose an additional risk because several agents that are used perioperatively (e.g., muscle relaxants, opioid analgesics, and nonsteroidal anti-inflammatory drugs) can induce acute mast cell degranulation. Prior surgical and anesthesia records should be obtained if available, and an appropriate strategy for the anesthetic management of the patient should be determined, with close communication involving the patient, anesthesiologist, surgeon, and an allergist.

Acute mast cell leukemia usually is treated with polychemotherapy as for acute myeloid leukemia (Chapter 168). Hematopoietic stem cell transplantation (Chapter 163) has yielded variable results for the treatment of mast cell disease, but occasional complete remissions have been reported. Non–mast cell clonal hematologic disorders associated with mastocytosis should be treated according to the standard-of-care guidelines for those disorders, regardless of the presence of mastocytosis.

Venom immunotherapy is recommended for patients who have a history of systemic reactions to Hymenoptera and who have evidence of IgE-mediated sensitization (by blood or skin allergy testing). Most experts recommend that such immunotherapy be continued indefinitely because fatalities have been reported after its discontinuation. If osteoporosis is detected by bone densitometry, it should be treated per standard recommendations (Chapter 225).

PROGNOSIS

The prognosis for mastocytosis varies by the category of disease. Most patients have an indolent course. At least 50% of patients with pediatric-onset cutaneous mastocytosis have complete resolution of the disease by adolescence, and the great majority of the other 50% of patients experience improvement or fading of the skin lesions.

Patients with indolent systemic mastocytosis and bone marrow mastocytosis usually have a normal life expectancy despite persistent symptoms, and progression to a more advanced category is unusual (less than 5% of cases). Factors associated with poorer prognosis includes the absence of urticaria pigmentosa, older age at onset of symptoms, an elevated level of serum lactate dehydrogenase or alkaline phosphatase, thrombocytopenia, anemia, peripheral blood smear abnormalities, and detectability of the D816V *KIT* mutation in peripheral blood.

The prognosis for systemic mastocytosis with associated hematologic neoplasm is determined by the prognosis for the associated hematologic disorder. Aggressive systemic mastocytosis and mast cell leukemia have poor prognoses, with median survival times of less than 3 years and less than 1 year, respectively. Prognostic factors associated with advancement into secondary mast cell leukemia or acute myeloid leukemia include age over 60 years, a hemoglobin concentration less than 10 g/dL, a platelet count less than 100,000/μL, or the presence of one or more mutations in *SRSF2*, *ASXL1*, and/or *RUNX1*.[16]

236 APPROACH TO THE PATIENT WITH RHEUMATIC DISEASE

VIVIAN P. BYKERK AND MARY K. CROW

DEFINITION

Rheumatic diseases are disorders of connective tissue in which general or localized inflammation is associated with pain, weakness, or loss of function attributable to joints, the spine, muscles, and/or related soft tissues. Systemic features and extramusculoskeletal features include stiffness, fever, weight loss, skin rashes, cardiopulmonary abnormalities, ocular inflammation, and renal dysfunction, often in distinct patterns, and are used to classify each disease.

Many of these diseases affect females more than males, with ankylosing spondylitis being a notable exception. This pattern is most striking in systemic lupus erythematosus (Chapter 245), which affects 8 to 10 women for every 1 man and typically has its onset in the childbearing years. Rheumatoid arthritis (Chapter 243) has a female-to-male ratio of approximately 3 : 1 and typically has its onset in the later adult decades.

Classification of Rheumatic Diseases

More than 100 types of rheumatic diseases have been described. Although the pathogenesis is usually dichotomized as degenerative or inflammatory, these diseases (Table 236-1) are usually subdivided as (1) diseases that are associated with degeneration of connective tissues attributable to trauma, structural/mechanical imbalances, or inherent early demise of cellular components; (2) diseases that are associated with systemic autoimmunity, often linked with measurable autoantibodies that can manifest primarily with synovitis, widespread organ involvement, inflamed blood vessels, or inflammation of muscle; (3) other inflammatory connective tissue diseases involving more dense tissues, not associated with the formation of autoantibodies, and hence termed *seronegative rheumatic diseases* or *spondyloarthropathies*; (4) diseases in which inflammation of the vasculature, particularly small, medium, or large arteries, is the predominant feature; (5) autoinflammatory diseases that can be associated with crystal deposition or genetic mutations involving cytokine pathways; and (6) pain syndromes that often must be considered in the context of these diseases, in which some syndromes appear to be comorbid and closely linked to the underlying rheumatic disease, such as diffuse pain associated with Sjögren syndrome, hypermobility of connective tissue, or regional pain syndromes that are anatomically linked to mechanical disruption. Patients who present with generalized pain syndromes require investigation to exclude a connective tissue disease. Increasingly, genomic phenotypes[1,2] are being associated with diseases as they have been categorized, and in some cases specific immunologic pathways and mediators have allowed grouping of a set of rheumatic diseases previously considered more distinct.

Mimics of rheumatic diseases exist, and clinicians must be mindful of considering these when evaluating a patient for a rheumatic disease. For instance, arthropathies and syndromes resembling a rheumatic disease can occur in the settings of both infection and malignancy. Autoimmune phenomena are increasingly being recognized in the setting of malignancy or as a consequence of treatment of malignancy with immune checkpoint inhibitors.[3] Red flags for each need to be considered in the assessment of a patient for possible rheumatic disease.

EPIDEMIOLOGY

In adults, the six prototypical rheumatic diseases most often assessed and managed by rheumatologists are rheumatoid arthritis (Chapter 243),[4] systemic lupus erythematosus (Chapter 245),[5] systemic sclerosis (Chapter 246), spondyloarthropathies (primarily ankylosing spondylitis and psoriatic arthritis; Chapter 244), Sjögren syndrome (Chapter 247), and vasculitis (Chapter 249). These diseases are ubiquitous throughout the world (Table 236-2), and for the most part they have a similar incidence globally. Autoimmune rheumatic diseases are also among the leading causes of death and morbidity in the industrial world, in part related to associated comorbid diseases, particularly cardiovascular disease, and they contribute to a significant socioeconomic burden. Increasing evidence points to risks for their genesis relating to environmental factors, socioeconomic factors, and exposure to infectious agents, ultraviolet radiation, and pollutants. Smoking, in particular, has been associated with an increased risk for systemic lupus erythematosus and rheumatoid arthritis in genetically susceptible individuals in Western cultures. Effects of migration elucidate some of these risks. For instance, Africans who migrate far away from their native environmental and cultural origins appear to have an increased susceptibility to systemic lupus erythematosus. Also, reports have linked occupational exposures, such as silica dust, mercury, pesticides, solvents, and metals, to an increased risk for systemic lupus erythematosus and rheumatoid arthritis.

In some cases, geographic clusters of a rare autoimmune disease indicate specific genetic determinants. For example, with systemic sclerosis, higher incidence, prevalence, and mortality rates have been reported in African American populations compared with White populations, and the prevalence has been reported as higher in southern Europe, particularly in Italy (prevalence of 7 to 33 per 100,000). Additionally, social and demographic factors may contribute to the epidemiology of rheumatic diseases. For example, the prevalence of systemic lupus erythematosus is reported as very high in Georgia, United States, whereas the prevalence of ankylosing spondylitis is rare in malaria endemic regions where HLA-B27 genotypes are rare. Inflammatory arthropathies, including

TABLE 236-1 COMMON RHEUMATIC DISEASES BROADLY CLASSIFIED ACCORDING TO PATHOGENESIS

DEGENERATIVE DISEASES OF JOINTS, BONE, AND SOFT TISSUES	SYSTEMIC AUTOIMMUNE DISEASES	SERONEGATIVE SPONDYLOARTHROPATHIES	VASCULAR RHEUMATIC DISEASES	AUTOINFLAMMATORY DISEASES	PAIN SYNDROMES
Osteoarthritis	Rheumatoid arthritis	Ankylosing spondylitis	ANCA- associated vasculitis	Adult-onset Still disease	Regional myofascial pain syndromes
Diffuse idiopathic skeletal hyperostosis (DISH)	Systemic lupus erythematosus	Psoriatic arthritis	Temporal artery vasculitis	Crystal diseases	Specific soft tissue syndromes (e.g., tendinopathies, enthesopathies, bursitis)
Degenerative disc disease	Sjögren syndrome	Reactive arthritis	Polymyalgia rheumatica	Pediatric periodic fever syndromes	Adhesive capsulitis
Spinal stenosis	Inflammatory myopathies (polymyositis, dermatomyositis)	Enteropathic arthritis	Behçet disease		Complex regional pain syndrome type 1 (reflex sympathetic dystrophy)
Osteoporosis	Systemic sclerosis				Hypermobility syndromes
					Fibromyalgia*

*The only pain disorder that has not been associated primarily with inflammation.
ANCA = antineutrophil cytoplasmic antibody; DISH = diffuse idiopathic sclerosing hyperostosis (also linked to metabolic factors, including elevated growth hormone).

ABSTRACT

Rheumatic diseases are common and an important cause of reduced quality of life, increased comorbidity, and reduced life expectancy. These diseases also result in a significant socioeconomic burden. A clinical-pathologic framework helps categorize patients who present with signs and symptoms suggestive of a rheumatic disease. A systematic approach to diagnosis and treatment can reduce the adverse clinical and economic consequences of these diseases.

rheumatoid arthritis and ankylosing spondylitis, have a higher prevalence in North American Native populations.

PATHOBIOLOGY

Rheumatic diseases are often referred to as *connective tissue diseases,* because connective tissue is most often the target of inflammatory and/or autoimmune processes. Connective tissue, which is the most abundant tissue in the body, supports and connects other tissues and organs and hosts immune cells and their mediators. Loose and dense connective tissues include cellular components and extracellular matrix. Loose connective tissue fills space between muscle sheaths and encases blood and lymphatic vessels. Reticular fibers provide the skeleton of muscle cells, nerves, and capillaries. Dense connective tissue supports the body's soft tissues and includes more collagen fibers and fewer cells. Connective tissue is found in the dermis, joint capsules, cartilage, bone, and fascia of muscles, and it forms tendons, ligaments, and points of connection where these insert into bone (aponeurosis). Some cells in connective tissue, such as mast cells or macrophages, are migratory, whereas some, such as fibroblasts, fibrocytes, and reticular cells, are resident cells. Fibroblasts are responsible for synthesizing collagen, elastic reticular fibers, and ground substance of extracellular matrix, including tissue fluids and collagen fibers. In health, connective tissue is integrated with cells associated with the body's defense system (e.g., lymphocytes, plasma cells, macrophages, dendritic cells, and eosinophils) and provides structure and support for the vasculature. However, the close proximity of connective tissue to blood vessels, the presence of innate immune cells, and the capacity for influx of immune cells under certain pathologic conditions make connective tissue the ideal setting for immune- and vascular-mediated diseases.

CLINICAL MANIFESTATIONS

Primary care and hospital-based health care providers are often the first to evaluate a patient with an evolving rheumatic disease, and they need to be attuned to the presenting features to make a timely diagnosis. The clinical manifestations of rheumatic diseases range from mild joint-related symptoms to life- or organ-threatening conditions. The presence of constitutional, systemic, and joint symptoms should always include rheumatic disease in the differential diagnosis.

Joint Symptoms as a Common Presenting Feature

Almost all rheumatic diseases can manifest with joint-related symptoms and signs. Typically, pain, stiffness, swelling, and difficulty with joint function are the main symptoms. In some forms of joint inflammation, erythema can be prominent, as in the case of autoinflammatory diseases such as gout or pseudogout (Chapter 252) and in infectious arthritis (Chapter 251).

The pattern of joint involvement, its particular distribution, the number of inflamed joints, the speed of onset, duration, and timing of maximal symptoms all provide clues to diagnosis. Regardless of pathogenetic subclassification, certain patterns can point to inflammatory immune-mediated arthritis, and others to a degenerative process. For instance, joint pain that is worse in the morning, associated with prolonged stiffness, and improves as the day goes on and with activity is a classic presentation of inflammatory joint disease such as rheumatoid arthritis (Chapter 243) or spondyloarthritis (Chapter 244). Conversely, pain that is worse with activity, better with rest, and associated with a short period of stiffness after resting, is typical of osteoarthritis (Chapter 241), which is a predominantly degenerative arthritis.

Location provides a clue to broad classification. Patients describing "pain all over" may have a primary pain syndrome. However, pain with an inflammatory pattern localized to the spine or an enthesis (site of ligament insertion) is more likely to indicate a seronegative spondyloarthropathy.

A patient presenting with an inflammatory pattern of symptoms predominantly involving the small joints of the hands and feet is more likely to have one of the autoimmune rheumatic diseases associated with either a positive antinuclear antibody (ANA), rheumatoid factor (RF) or anti–citrullinated peptide antibody (ACPA). Asymmetric large and small joint pain, swelling, and erythema are more characteristic of psoriatic arthritis. Joint symptoms do not always indicate joint disease. Although a third of people might report having a form of debilitating arthritis, these symptoms can include periarticular and soft tissue syndromes common to many rheumatic diseases. The various locations of articular and nonarticular patterns of pain (Chapter 26; Fig. 236-1), including involvement of tendons, ligamentous insertions, and fascia, as well as the organ involvement that is typical of specific rheumatic diseases,[6] highlight the need to assess physical manifestations when making a diagnosis of any rheumatic disease.

Nonspecific Clinical Presentations

When present in the context of fever or cutaneous manifestations, including rashes, vasculitis and systemic lupus erythematosus (Chapter 245) must be considered. Sicca symptoms, though pathognomonic of Sjögren syndrome (Chapter 247), can occur concurrently in patients with systemic lupus erythematosus. Systemic features such as myalgias or fatigue are common to almost all rheumatic diseases regardless of their classification, but true muscle weakness may be the only presenting complaint of an inflammatory myopathy (Chapter 248). Renal involvement is common in seropositive systemic autoimmune diseases and vasculitis.

Cutaneous Manifestations

Although cutaneous manifestations are frequent in patients with seropositive autoimmune diseases, particularly systemic lupus erythematosus (Chapter 245), they are important manifestations of all autoimmune diseases. A nonblanching purpuric rash can indicate a vasculitis, and rashes involving specific extensor regions are common to dermatomyositis (Chapter 248). In cases of systemic lupus erythematosus or dermatomyositis, rashes are triggered or worsened by exposure to ultraviolet light and occur in a light-exposed distribution. Rashes of vasculitic origin can indicate either the presence of an autoimmune disease such as systemic lupus erythematosus or an inflammatory vascular disease such as antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis. These rashes tend to be present for days and are often palpable, and a tissue biopsy of the lesions will be very helpful in diagnosis. Rashes can be transient. In adult-onset Still disease (an adult form of systemic inflammatory arthritis classified as an autoinflammatory disease; Chapter 240), patients present with daily spiking fevers, peaking late in the day, associated with a salmon-colored evanescent blanching rash lasting only 1 to 2 hours. The specific location of a rash aids in diagnosis. A facial rash that spares the nasolabial folds is classic for lupus. A rash that does not spare the nasolabial folds suggests rosacea. Psoriasis is almost always present in psoriatic arthritis (a spondyloarthropathy variant). Although psoriasis is often widespread, involving extensor surfaces, it can be missed if there are very few lesions or if it is located in areas that are not easily seen (intertriginous regions, such as in the ear, umbilicus, buttock creases,

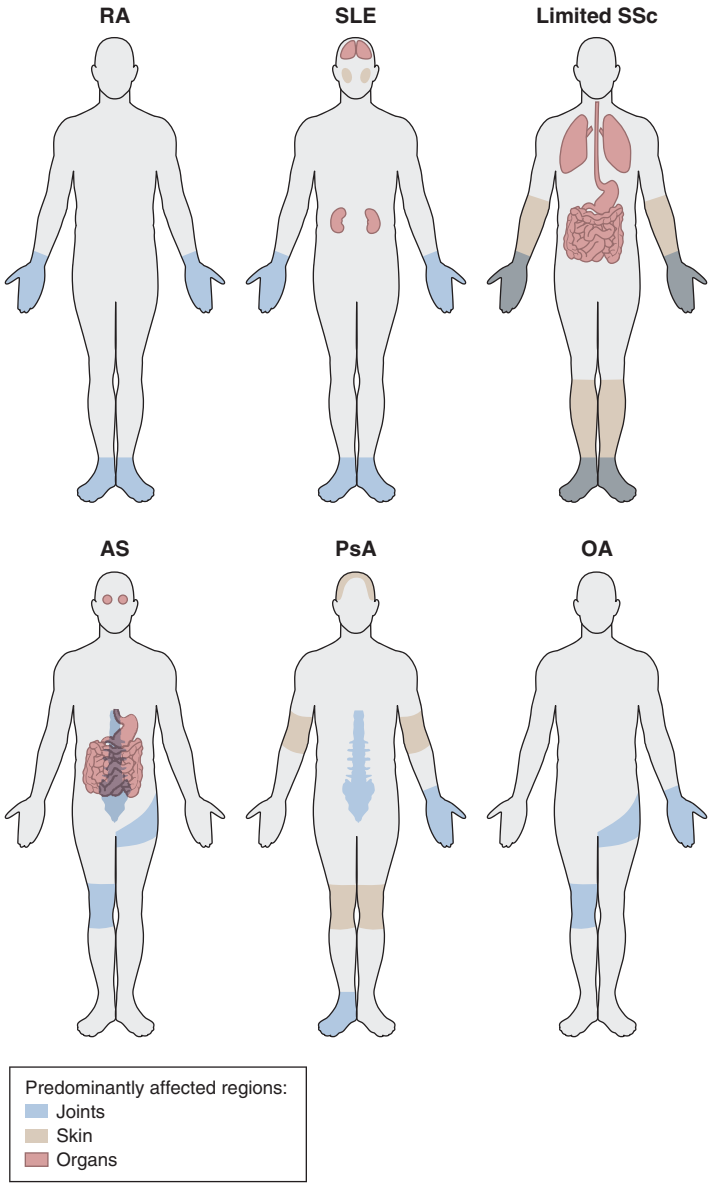

FIGURE 236-1. Patterns of joint and organ involvement in rheumatic disease. Characteristic patterns of joint and organ distribution and involvement distinguish among rheumatic diseases and aid in diagnosis. AS = ankylosing spondylitis; OA = osteoarthritis; PsA = psoriatic arthritis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; SSc = systemic sclerosis. (From Ospelt C, Frank-Bertoncelj M. Why location matters: site-specific factors in rheumatic diseases. *Nature Rev Rheumatol*. 2017;13:433-442.)

or scalp) or if it involves only the nails. The rash of psoriasis can be seen in any of the variants of the spondyloarthropathies. Occasionally rheumatoid arthritis (Chapter 243) will manifest with nodules over the extensor surfaces; however, nodules over extensor surfaces may also indicate gouty tophi (Chapter 252).

Skin tightness is the hallmark of systemic sclerosis (Chapter 246), often referred to as scleroderma, which most often involves the extremities. Patients typically present initially with swelling of the digits, followed by tightness of the hands and ultimately tightness of the skin. Raynaud phenomenon, though not specific to systemic sclerosis, frequently precedes its onset, often by many years. Skin tightness can progress to involve the face, arms, and, in the case of diffuse systemic sclerosis, trunk, back, and legs. Distal tightening of the skin, presence of telangiectasias, and digital ulcers can be seen.

Systemic Manifestations

Rheumatologic diseases eventually can involve every organ system but particularly can cause glomerulonephritis (Chapter 113, especially systemic lupus erythematosus), interstitial lung disease (Chapter 80, especially in systemic sclerosis and rheumatoid arthritis), renovascular disease (Chapter 110, especially systemic sclerosis), pericardial and pleural disease (Chapters 62 and 86, especially systemic lupus erythematosus),[7] and neurologic manifestations (especially systemic lupus erythematosus).

Specific Clinical Scenarios

Degenerative Rheumatic Diseases

Degenerative joint diseases, which are associated with advancing age, mainly include osteoarthritis (Chapter 241) and degenerative disc disease (Chapter 369). In general, these disorders are not associated with rashes or nonspecific constitutional symptoms.

Autoimmune Rheumatic Diseases

Autoimmune rheumatic diseases include systemic lupus erythematosus, rheumatoid arthritis, systemic sclerosis, primary Sjögren syndrome, idiopathic inflammatory myositis, and the systemic vasculitides. These diseases involve multiple organ systems and are heterogeneous in their clinical manifestations. Each symptom is associated with specific signs. Cutaneous manifestations, sicca symptoms (of dry eyes or mouth), mucosal ulceration, fevers, alopecia, and Raynaud syndrome are common and often described by patients. These symptoms can occur alone or in addition to symptoms affecting the joints and muscles.

Spondyloarthropathies

Ankylosing spondylitis (Chapter 244), which manifests with lower spine disease and earlier spinal fusion, is more common in males than females. Sacroiliitis is the hallmark of this disease. Disease in females may present more atypically with cervical or thoraco-lumber symptoms. Localization of symptoms to the neck and thoraco-lumbar spine, sacroiliac joints, large upper and lower extremity joints, and nerve roots can be used to differentiate ankylosing spondylitis from rheumatoid arthritis. The typical presence of psoriatic skin lesions in patients with psoriatic arthritis can be a distinguishing feature from rheumatoid arthritis. Spinal inflammation also can be associated with inflammatory bowel disease (Chapter 127), not infrequently in the mid or upper spine as opposed to the sacroiliac joints.

Vasculitis

The vasculitic syndromes are generally grouped based on the size of the involved vessel (Chapter 249). Polymyalgia rheumatica (Chapter 250) is a common inflammatory rheumatic disease of the elderly and shares many pathogenetic and epidemiologic features with giant cell arteritis, a form of older-onset vasculitis. Patients complain of aching around the neck and bilateral involvement of the shoulder and hip girdles, along with significant stiffness that is most problematic in the morning. The onset of symptoms can be abrupt or insidious over weeks to months.

Autoinflammatory Diseases

Gout (Chapter 252), which is the most common and prototypical autoinflammatory disease, occurs more often in middle-aged and older men and is increasing in prevalence. An exquisitely painful joint with periarticular erythema and swelling are presenting features. Tophi that might be confused with rheumatoid nodules can be seen. Calcium pyrophosphate deposition disease (pseudogout) can have a similar presentation. Rare autoinflammatory diseases (Chapter 240) based on mutations in genes involved in inflammatory pathways are more typically diagnosed in children.[8]

Pain and Pain Syndromes

Pain (also see Chapter 26) is a common and nonspecific, but very important, symptom central to nearly all rheumatic diseases. The location, distribution, and patterns of pain should be elicited, along with temporal features, triggers, migratory or alleviating features, and prior history of physical or psychological trauma. In regional pain syndromes (Chapter 26), the distribution of pain is the key clue to the diagnosis. Diffuse pain without evidence of underlying pathology associated with inordinate levels of fatigue, difficulty coping, and intricately detailed descriptions of pain using colorful analogies herald fibromyalgia (Chapter 253).

Most pain syndromes are regional nociceptive pain syndromes. For instance, a regional pain syndrome relating to a mechanical neck and shoulder structural problem will result in the patient having pain not only in the neck and involved shoulder but also the trapezius, upper chest, axilla, and upper and/or lower arm and hand. A large proportion of patients who present with musculoskeletal pain will have regional pain relating to muscular imbalances or postural factors with or without a degenerative arthritis. Regional pain can be associated with a combination of muscular spasm, atrophy, and secondary impingement of tendons. Pain in a distal extremity after trauma

or surgery associated with a cold shiny extremity is suggestive of complex regional pain syndrome.

DIAGNOSIS

A comprehensive history is key to an evaluation of a patient with a rheumatic disease. In addition to considering age and gender, a patient's personal history, including marital status, occupation, and psychosocial factors, helps to elucidate a patient's diagnosis, prognosis, and treatment options. Specific clues can be helpful in making a diagnosis of one of the rheumatic diseases (Table 236-3).

Assessing clinical signs and symptoms is the cornerstone of diagnosis. Most rheumatic disorders will present with symptoms that involve, or seem to involve, joints. Pain can be limited to a specific joint or group of joints or periarticular structures. Querying the patient to determine the pattern of symptoms—whether pain, swelling, or stiffness associated with joints—is key to narrowing the differential diagnosis of a rheumatic disease. Joint symptoms should be assessed for inflammatory features such as prolonged stiffness, pain at rest, or noninflammatory and mechanical features, such as instability or giving way, locking, or increased symptoms with use. Patterns of joint involvement (see Fig. 236-1)—whether primarily small joints of the hands, wrist, and feet; large joints of the elbows, knees, ankles, or "root" (shoulders or hips); or spinal involvement—will further point to a specific diagnosis. Moreover, questions regarding recent illnesses, travel, exposure to possible infectious pathogens, and presence or absence of systemic features such as fever, fatigue, or weight loss will provide important clues. Appreciation of signs and symptoms indicating extra-articular features, particularly cutaneous, pulmonary, renal, neurologic, or vascular manifestations, will guide the differential diagnosis, and further investigations will help to determine the definitive diagnosis as well as the prognosis and required intensity of therapy.

The presence of one rheumatic disease can be associated with comorbid manifestations unrelated to connective tissue. For example, myocardial infarction is more common in many patients with rheumatic diseases. Immobility or treatment-related factors leading to obesity can increase risks for diabetes and lower joint degeneration.

The Medical History

Age and Gender

Rheumatic diseases that typically manifest in childhood include genetically based disorders, such as hemophilia associated with arthritis and a number of autoinflammatory conditions. Juvenile idiopathic arthritis refers to forms of arthritis in which the onset occurs before the age of 16 years. Autoimmune rheumatic diseases and inflammatory rheumatic diseases (e.g., spondyloarthropathies, rheumatoid arthritis,[9] and systemic lupus erythematosus) can begin in the teenage years or in young adulthood, whereas degenerative conditions such as osteoarthritis rarely begin to manifest until later in life. The peak onset of rheumatoid arthritis occurs in the late middle years, although onset can occur at almost any time in life. Elderly people are more prone to polymyalgia rheumatica, but it should be considered at all ages. Autoimmune diseases are more common in women, whereas spondyloarthropathies can be equally common in men and women. Gouty arthritis is more common in men and rarely attacks women before menopause.

Occupation and Recreation

Occupation and recreational activities may give rise to physical and psychological stresses. The demands of a patient's occupation need to be understood, particularly when repetitive activities may contribute to the development of degenerative joint disease or to regional pain syndromes. Similarly, trauma and repetitive actions from sports, including prior injuries, can be a significant contributor to degenerative joint disease.

Family History

It is important to obtain a complete family history because autoimmune diseases, spondyloarthropathies, and gout occur with an increased incidence in families. It is common to see family pedigrees in which different forms of autoimmunity occur throughout a family. Also, generalized osteoarthritis that involves the hands and other joints commonly runs in families.

Concomitant Medication Use

A careful medication history is essential because concomitant medications may contribute to the genesis of a rheumatic disease. For example, diuretics can increase hyperuricemia and the risk for gouty arthritis. Minocycline, hydralazine, and rarely isoniazid can be associated with lupus-like presentations. Antibiotics in the fluoroquinolone class have been associated with enthesopathies.

Habits and Social Circumstances

Smoking has increasingly been associated with rheumatoid arthritis and systemic lupus erythematosus. Poor socioeconomic circumstances and psychosocial or physical stress may contribute to the severity of symptoms or access to care and should be considered in planning management strategies.

TABLE 236-3 CLINICAL FEATURES AND CLUES TO FACILITATE DIAGNOSIS FOR EACH CATEGORY OF RHEUMATIC DISEASE

DEGENERATIVE DISEASES OF JOINTS, BONE, AND SOFT TISSUES	SYSTEMIC AUTOIMMUNE DISEASES	SERONEGATIVE SPONDYLO-ARTHROPATHIES	VASCULAR RHEUMATIC DISEASES	AUTOINFLAMMATORY DISEASES	PAIN DISORDERS
Investigate if persistent symptoms of pain >6 wk or failure of conservative measures (physical therapy, NSAIDs) If at risk for bone loss and fragility fracture, consider osteoporosis	Often manifest with inflammatory joint pain and/or swelling, constitutional symptoms, skin manifestations, multiorgan involvement Perform ANA, RF, ESR, CRP	Consider if these features are present: psoriasis, inflammatory back pain, known associated nonarticular features (e.g., uveitis, inflammatory bowel disease, urethritis, enthesitis, dactylitis)	Consider if the following are present: infarcted tissue, vasculitic rashes, pulmonary hemorrhage, acute or subacute renal syndromes	All can present with fever Genetically determined. Mediated by cytokines— e.g., interleukin-1 or TNF-α In adults, consider crystal diseases	Consider if pain is in excess of findings, if history of resolved trauma or repetitive strain, referred pain symptoms, diffuse pain, if high pain levels
INITIAL INVESTIGATIVE APPROACH TO CONFIRM SUSPECTED RHEUMATIC DISEASE IN EACH CATEGORY					
Image specific region associated with persistent pain (consider additional imaging in areas that may be referring pain) If osteoporosis is a concern, perform BMD and investigate using laboratory tests, including calcium, 25-OH D, and/or PTH to begin evaluation for metabolic bone diseases	Investigations should specifically target suspected diseases Specific testing should include CK if weakness or myalgia; anti-CCP (ACPA) and RF if synovitis is present; ANA in screening rheumatic disease, and dsDNA, C3, C4, ENA if SLE or sicca symptoms present	Imaging of sacroiliac (SI) joints (radiographs if long-standing symptoms, MRI if more recent onset) HLA-B27 testing if inflammatory back pain or SI pain most predominant, clinical suspicion high for inflammatory back pain, but imaging is negative	Laboratory testing should include ANCA Anti-PR3 Anti-MPO Acute phase reactants (ESR, CRP) Tissue sampling of involved organs to facilitate pathophysiologic classification	For suspected crystal disease, perform aspiration of synovial fluid or tophus and examine under polarized light microscopy	Usually a diagnosis of exclusion, based on physical examination In complex regional pain syndrome, tendonitis or enthesitis, specific physical findings and imaging can facilitate diagnosis

25-OH D = calcitriol; ACPA = anti–citrullinated peptide antibodies; ANA = antinuclear antibodies; ANCA = antinuclear cytoplasmic antibodies; anti-CCP = anti–cyclic citrullinated peptide; anti-MPO = anti-myeloperoxidase; anti-PR3 = anti-proteinase-3; BMD = bone mineral density scan; CK = creatinine phosphokinase; CRP = C-reactive protein; dsDNA = anti–double-stranded DNA; ENA = antibodies to extractable nuclear antigens (e.g., Ro, La, Sm, RNP, Scl70, Jo-1); ESR = erythrocyte sedimentation rate; MPO = myeloperoxidase; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs; PR3 = proteinase 3; PTH = parathyroid hormone; RF = rheumatoid factor; SLE = systemic lupus erythematosus; TNF-α = tumor necrosis factor-α.

Onset and Evolution of Symptoms

Knowledge of the pattern of onset, location, and evolution of symptoms is essential to make an accurate diagnosis of a rheumatic disease. Symptoms that develop over hours to days typically suggest an inflammatory, infectious, or traumatic process. When symptoms persist for more than 6 weeks, the onset is considered subacute, and the disease is considered chronic. Early in the presentation of some rheumatic diseases, the symptoms can be intermittent or palindromic before becoming constant. In patients who have the sudden onset of joint pain and swelling, particularly involving one or a few joints, an infectious or crystalline etiology should be considered.

Pain and Stiffness

The assessment of pain should include a description of its onset, constancy/chronicity, severity, quality, factors that trigger or improve it, and location and radiation of the pain. Stiffness, often described as tightness or linked to difficulty with movement or function, should be determined in terms of location (e.g., is it in a particular joint or more diffuse) and timing and duration (e.g., occurring after a period of rest). Stiffness that resolves in 10 to 15 minutes is more characteristic of osteoarthritis. In inflammatory disease, stiffness typically lasts longer, often at least 1 hour and even all day.

Specific Joint Symptoms

The distribution of joint involvement is key to making a diagnosis of a rheumatic disease (see Fig. 236-1). Monoarthritis describes symptoms in a single joint; oligoarthritis (or pauciarthritis) refers to symptoms in two to four joints; and polyarthritis indicates involvement of at least five joints. Peripheral arthritis involves an extremity, whereas spinal involvement is termed axial disease. Symmetrical as opposed to asymmetrical peripheral joint disease is more commonly associated with autoimmune rheumatic disorders, whereas asymmetrical arthritis can be associated with spondyloarthropathies or osteoarthritis. Similarly, predominant small joint involvement is more typical in rheumatoid arthritis or systemic lupus erythematosus, whereas large joint involvement is classic for spondyloarthropathies. In addition, the presence of associated enthesitis and axial symptoms herald spondyloarthropathy. Joint or spine symptoms associated with inflammatory causes often include predominance of symptoms in the morning, associated with stiffness for more than 60 minutes, worsening with rest, and improvement over the day and with activity. Joint or spine symptoms associated with degenerative joint disease typically worsen with activity, are often worse later in the day, are associated with stiffness, and typically resolve quickly over 15 to 30 minutes. Joint pain is usually felt at the joints (exceptions include shoulder pain, felt over the deltoid, and hip pain, felt in the groin). Joint pain from degenerative or inflammatory causes can vary in severity. Most patients will describe joint pain as aching and rarely rate the pain higher than 8/10 on an ascending severity scale unless they experience acute synovitis. Pain relating to localized myofascial pain syndromes, including tendinopathies and enthesopathies, may be described as arthritis, but it extends from joints and worsens with specific movements. In people suffering from centralized generalized pain syndromes, pain is often rated very highly (10/10), often with pain descriptions including qualifiers to impress the severity of the pain: "like a truck ran over me," is poorly localized, and is diffusely present (involving upper and lower body regions).

Effect on Activities

It is important to ask patients how their condition has affected their activities and even their mental health. Rheumatic diseases result in work disability, job loss, disruption of social relationships, and financial instability. Reduced social participation without a strong personal support system is associated with worsening of mental health (isolation, depression, anxiety), worse prognosis, and even early mortality. Function should be assessed in terms of a patient's ability to perform activities of daily living, work, and participation. Validated questionnaires of function are available to identify functional limitations.

Physical Examination

A complete examination by a physician is required to identify and classify a rheumatic disease. The examination should include an assessment of constitutional symptoms such as temperature, body mass index, affect, pain behaviors, gait, and posture, as well as organ-specific examination of the scalp, skin, eyes, lymphatic system, cardiovascular system, lungs, abdomen, joints, spine, and skeletal muscles. A systematic joint examination is key to the rheumatic disease examination and should include all regions, with comparisons of right and left sides. The pattern of joint involvement, including symmetry and axial versus peripheral involvement should be recorded. Use of a joint diagram (homunculus) helps to track joint involvement. The joint examination should include documentation of the presence or absence of tenderness, periarticular wasting, erythema, swelling, limitation in range of motion (ROM), sites of prior surgery and trauma, and joint deformity, allowing for comparison over time and between different examiners. A four-step systematic approach to joint examination should include (1) inspection (looking for asymmetry, erythema, swelling, and deformity), (2) palpation (feeling for tenderness, specifically joint line tenderness, warmth, synovial thickening and effusion, bony hypertrophy, and crepitus), (3) ROM (both active and passive for each joint), and (4) special tests specific to each joint or region. A complete examination should also consider relevant extra-articular manifestations.

The physical examination can distinguish between arthralgia (a complaint of joint pain and tenderness without heat, or swelling) and arthritis, in which pain and tenderness are associated with signs of joint swelling and warmth (synovitis), deformity, or limitation of movement. A finding of redness (erythema) can indicate more acute and/or severe inflammation. The presence of erythema is more typically seen in the case of infection or crystalline (autoinflammatory) arthritis. Joint warmth also signifies underlying inflammation. Joint swelling, a definitive sign of joint inflammation or arthritis, may indicate the presence of a joint effusion (excess synovial fluid) or synovial thickening indicating an active inflammatory process involving increased vascularization, cellular recruitment, transudate, and edema in the synovial membrane (synovitis). All rheumatic diseases except neurologically mediated pain syndromes can present with synovitis.

Palpable bony thickening around a joint, particularly distal or proximal phalangeal joints or first metacarpal joints, is due to bone reaction and proliferation or osteophytes, characteristic of osteoarthritis. Examiners should palpate for crepitus, which feels like a grinding sensation under the examiner's hand during active or passive joint motion. Fine or velvety crepitus may indicate chronic proliferative synovitis, whereas coarse crepitus may indicate either roughening of the cartilage surface or complete loss of hyaline cartilage with bone moving on bone. In some diseases such as rheumatoid arthritis, psoriatic arthritis, or Jaccoud arthropathy (a form of systemic lupus erythematosus–related deforming arthropathy), deformity occurs as a result of joint subluxation or contracture related to nature's forces on weakened, lax, distended joint capsules and lax ligaments and tendons as a consequence of chronic swelling from synovitis. Muscle atrophy can occur around arthritic joints and contribute to perceived weakness or instability.

Assessing Range of Motion

Both active and passive range of motion should be assessed to appreciate joint function. Generally, active range of motion is assessed first by asking patients to demonstrate full movement of a joint; active range of motion requires intact strength, innervation, muscle and tendon function, and joint mobility. Passive range of motion is assessed by determining joint mobility or, in some cases, ligament or tendon impingement. First, assessing active range of motion enables the examiner to appreciate potential areas of pain and where to examine carefully. If mobility is full-on passive range of motion, other causes can be considered for loss of mobility.

Establishing a Specific Diagnosis

The findings from a thorough history and physical examination, along with an appropriate set of investigations, can be used to guide diagnosis (see Table 236-3 and Fig. 236-2). Most rheumatic diseases appear spontaneously and often insidiously or with a subacute onset. Not all will manifest with all typical features at the time of presentation, and a diagnosis can take time to make as defining features present themselves. Furthermore, features may evolve sequentially over time, so rheumatic diseases from more than one category must often be considered in a patient whose disease has not yet fully manifested. When a specific diagnosis is uncertain, features should be considered in the context of the broad classifications, and terms such as *undifferentiated inflammatory polyarthritis* or *undifferentiated spondyloarthropathy* may be used in the interim to aid in diagnosis and management. When a patient's disease is not yet diagnosed, investigations and monitoring over time can help to identify a rheumatic disease as it evolves in a patient. Autoimmune and vascular rheumatic diseases are associated with high morbidity and mortality when left untreated, so timely diagnosis and initiation of therapy have significant impact on patient outcome.

The evaluation of regional pain syndromes requires a careful history of pain features, as well as a medical history, physical examination, and consideration of "red flags" or factors that indicate a more sinister pathology specific to a related organ from which pain can be referred. Pain in the setting of a history of malignancy should suggest the possibility of metastases. A tick bite may

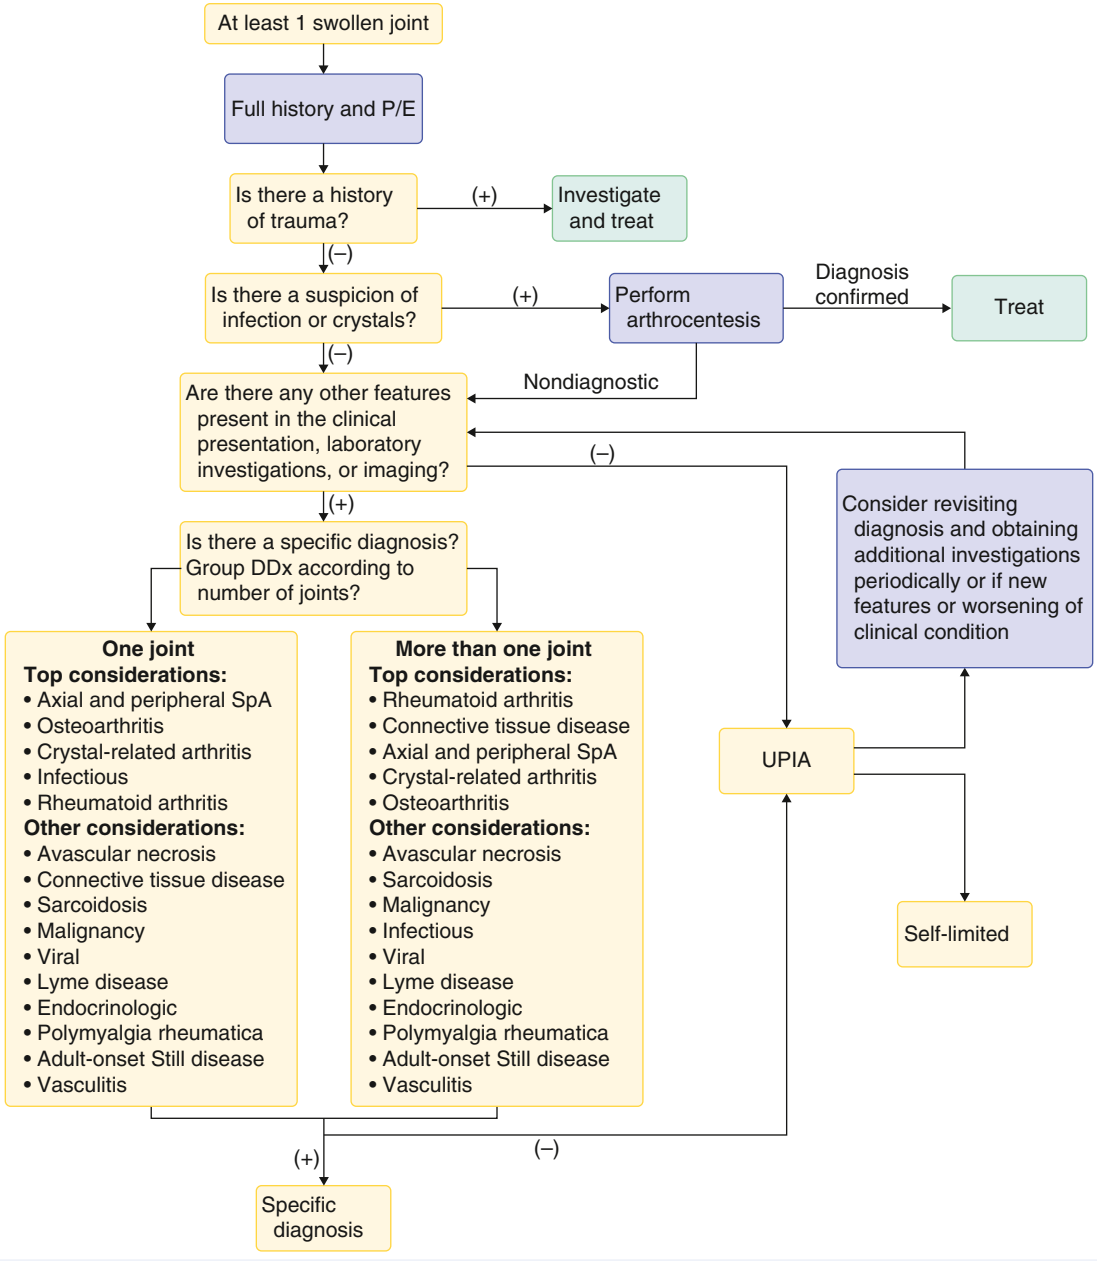

FIGURE 236-2. Algorithm for identification of undifferentiated peripheral inflammatory arthritis. Recommended minimum investigations in all patients: rheumatoid factor and/or anti–citrullinated peptide antibodies, erythrocyte sedimentation rate and/or C-reactive protein, complete blood count, and radiographs of affected joints. DDx = differential diagnosis; P/E = physical examination; SpA = spondyloarthritis; UPIA = undifferentiated peripheral inflammatory arthritis. (From: Hazlewood G, Aletaha D, Carmona L, et al. Algorithm for identification of undifferentiated peripheral inflammatory arthritis: a multinational collaboration through the 3e initiative. *J Rheumatol Suppl*. 2011;87:54-58.)

indicate prior Lyme disease (Chapter 296). Dermatomal distributions are seen with disc herniations or shingles. Most pain syndromes warrant a full medical evaluation before making a definitive diagnosis.

Autoimmune rheumatologic diseases should be further characterized by additional investigations (see Table 236-3), including measurement of characteristic autoantibodies in serum. Defined autoantibody specificities can discern subtypes of rheumatic diseases (Chapter 237, Table 237-1).

The diagnosis of polymyalgia rheumatica (Chapter 250) is primarily clinical, but includes laboratory evidence of acute-phase reactants. Mimics of polymyalgia rheumatica can include elderly-onset rheumatoid arthritis, so tests to exclude rheumatoid arthritis (Chapter 243) may be indicated. When considering polymyalgia rheumatica, giant cell arteritis should be in the differential diagnosis, particularly when acute-phase reactants are very high or musculoskeletal symptoms or manifestations are absent. A high index of suspicion for temporal artery inflammation or large vessel disease involving the aorta is needed so tissue diagnosis can be made in giant cell arteritis before it progresses to blindness, stroke, or severe vascular destruction with organ ischemia.

Diagnosis of the specific autoimmune disease is more challenging when presenting features overlap among diseases. One or more of certain features, including constitutional disturbances such as fatigue, fever, weight loss, arthralgia, arthritis, and myalgias are commonly seen in almost all rheumatic diseases. Sicca symptoms, which are the prototype of primary Sjögren syndrome (Chapter 247) and associated with Sjögren syndrome's specific autoantibody patterns, can occur concurrently in systemic lupus erythematosus and rheumatoid arthritis. Autoimmune vasculitides and systemic lupus erythematosus can share similar organ system manifestations, including involvement of the lungs, kidneys, skin, and nervous system. In some cases, tissue biopsy may help to provide a definitive answer.

Consensus

Diagnostic criteria have been established for most rheumatologic diseases (see specific chapters), but a diagnosis can be made without meeting all classification criteria because some features of a rheumatic disease are highly specific and are not associated with other diseases. By using this algorithm, patterns, and clinical findings (see Table 236-2), clinicians can hone in on a differential diagnosis and then use investigations to confirm the suspected diagnosis.

Laboratory and Imaging in Rheumatic Diseases

Identifying the presence of specific laboratory or imaging features can support a diagnosis and aid in specific classification of a rheumatic disease. For example,

a high serum uric acid level is associated with gout, though levels may lower during acute attacks. A positive antinuclear antibody test (Chapter 237) is nonspecific,[10] but testing ANCAs or imaging the vascular tree of an involved area can be key to establishing a diagnosis in patients with vasculitis.[11,12] Similarly, radiographic imaging of the sacroiliac joints of patients who have seronegative spondyloarthropathies when symptoms are sustained or MRI if the disease is of more recent onset is key. Radiographs and MRIs (Chapter 238) of specific joint areas not only help establish the diagnosis but also aid in staging the disease. In the case of rheumatoid arthritis, testing of rheumatoid factor and ACPA is critical. For other seropositive systemic rheumatic diseases, disease-specific autoantibodies can be very informative. However, some autoimmune diseases are seronegative,[13] and it can be hazardous to diagnose a rheumatic disease based on a single laboratory finding, because a constellation of findings is typically always required.

TREATMENT

The treatment approaches to each rheumatic disease differ (see Chapters 240 to 254). Therapeutic approaches to degenerative rheumatic diseases focus on control of symptoms of pain with either nonsteroidal anti-inflammatory drugs or analgesics. Physical modalities, strengthening, and encouraging activity are a key part of managing degenerative arthritis; at times, injections of glucocorticoids or other agents can manage symptoms. When conservative approaches fail, orthopedic surgery is warranted.

By comparison, the approach to systemic and inflammatory rheumatic diseases usually requires more intense or immunomodulatory therapies. Glucocorticoids are a major component of treatment regimens, particularly when organs are at risk, when other agents take time to become fully effective, and in situations in which no alternative therapeutic options are available. However, glucocorticoids carry their own risks and must be used with discretion. When glucocorticoids are used, they should be tapered as soon as possible and then used again only for disease exacerbations. Depending on the disease, glucocorticoid-sparing therapies are usually initiated early, with potency tailored to the severity and risk for the illness itself, while considering patients' other comorbid conditions and other medications being used. For example, systemic lupus erythematosus patients (Chapter 245) presenting with only a rash or synovitis may require a relatively weak agent, such as hydroxychloroquine,[14] whereas patients with renal disease may need mycophenolate mofetil, cyclophosphamide, or other parenteral immunomodulatory therapies to treat that disease manifestation effectively. Similarly, in rheumatoid arthritis (Chapter 243), patients who present with high-titer ACPA levels, a high swollen joint count, and erosions on radiographs of the hands and feet are candidates for rapidly escalating doses of methotrexate with or without other disease-modifying antirheumatic drugs and early use of biologic or targeted synthetic drugs (see Chapter 29).

LABORATORY TESTING IN THE RHEUMATIC DISEASES

KEVIN D. DEANE AND DAVID S. PISETSKY

The rheumatic diseases are a diverse group of conditions that affect the musculoskeletal system as well as other organs, where they cause inflammation, damage, and functional impairment. These conditions range from mild joint pain to severe life-threatening manifestations such as systemic vasculitis and rapidly progressive renal failure.

The first steps in the diagnostic process include a detailed history, physical examination (especially focused on the joints), and basic laboratory tests to determine findings suggestive of inflammation as well as the extent of involvement of organ systems (e.g., kidneys). These basic tests can then be followed by evaluation of biomarkers that are indicative of specific diseases. In addition to their value in establishing a diagnosis, laboratory tests can help assess the activity or severity of a rheumatic disease, its prognosis, and the effects of therapy, including drug toxicity.

MARKERS OF INFLAMMATION

For many patients, the initial goal of laboratory testing is to determine the presence of inflammation (Chapter 36). The immediate response to inflammatory stimuli is termed the *acute phase response* and includes a set of proteins produced primarily in the liver in response to cytokines such as interleukin-6 (IL-6), tumor necrosis factor-α (TNF-α), and IL-1.

Although cytokines and chemokines can be measured in some commercial assays,[1] the most common clinical measures of the acute phase response are the C-reactive protein (CRP) level and the erythrocyte sedimentation rate (ESR). CRP levels provide a nonspecific but useful measure of inflammation of any cause, so they must be interpreted carefully in the evaluation of rheumatic diseases, especially when using high-sensitivity assays that can measure very low concentrations of CRP. Since CRP levels can rise and fall quickly, with a half-life of 5 to 7 hours, the level of this protein can provide a useful measure of disease activity and response to treatment.

The ESR is an indirect measure of acute phase reactants such as fibrinogen, whose production is increased in inflammatory states. The ESR has been traditionally determined using manual approaches such as the Westergren method, which measures the rate of fall of red blood cells (RBCs) in anticoagulated blood in a capillary tube over 60 minutes; in this assay, increased levels of proteins in plasma lead to a faster fall of RBCs. Automated methods to calculate the ESR have good correlation with the Westergren method.[2] The ESR is nonspecific and also depends on the age and sex of the person. In addition, a low CRP but high ESR may indicate a paraproteinemia. Since ESR levels can be slower to change than CRP levels, CRP determinations may be superior to assess the effects of treatment in some settings.

Other molecules, such as serum amyloid protein, fibrinogen, and complement, also are markedly increased during the acute phase response. Patients with inflammation frequently exhibit a leukocytosis or thrombocytosis, most likely reflecting the action of cytokines and other mediators such as glucocorticoids. With chronic inflammation, low albumin levels and anemia of chronic disease can also occur. In systemic lupus erythematosus, lymphopenia, thrombocytopenia, and low CRP values often characterize active disease, with the discordance between laboratory and clinical findings a clue to diagnosis.

LABORATORY EVALUATION OF ARTHRITIS AND RELATED DISEASES

One of the most common presentations of rheumatic diseases is pain in and around the joints, collectively called arthralgia or arthritis. The extent of inflammation varies markedly, however, with some forms such as osteoarthritis (Chapter 241) showing only limited evidence of inflammation either locally or systemically.

If inflammatory arthritis is suspected, further testing depends on the type and distribution of joint involvement. If arthritis is present in only one or two joints, joint aspiration to evaluate for infection or crystal-induced disease is typically indicated, especially for acute disease with evidence of severe inflammation such as fever or joint swelling and redness. Measuring the serum uric acid level is usually not helpful in diagnosing acute gout. Blood cultures can provide important information in assessing the presence of joint infection if joint aspiration cannot be performed.

If polyarticular inflammatory arthritis is suspected, laboratory tests often lead to a correct diagnosis. Since rheumatoid arthritis is the most common form of inflammatory polyarthritis in adults, autoantibody tests for it are typically indicated (e.g., rheumatoid factor and antibodies to citrullinated protein antigens).

RHEUMATOID FACTOR

Rheumatoid factor comprises a family of antibody specificities that bind to the immunoglobulin G (IgG) molecule and react with antigenic determinants that are most likely conformational in origin in the Fc portion.[3] IgM rheumatoid factors are the most abundant of these antibodies. Rheumatoid factors occur in approximately 60 to 80% of patients with rheumatoid arthritis (Chapter 243) and represent one criterion for the classification or diagnosis of this disease. Furthermore, high levels of rheumatoid factors are often associated with the presence of joint erosion, joint deformity, and a worse prognosis.

Rheumatoid factors also can occur in individuals with a wide range of autoimmune, inflammatory, and infectious diseases (e.g., bacterial endocarditis [Chapter 61]), as well as in normal individuals, especially as they age. The

LABORATORY TESTING IN THE RHEUMATIC DISEASES

KEVIN D. DEANE AND DAVID S. PISETSKY

The rheumatic diseases are a diverse group of conditions that affect the musculoskeletal system as well as other organs, where they cause inflammation, damage, and functional impairment. These conditions range from mild joint pain to severe life-threatening manifestations such as systemic vasculitis and rapidly progressive renal failure.

The first steps in the diagnostic process include a detailed history, physical examination (especially focused on the joints), and basic laboratory tests to determine findings suggestive of inflammation as well as the extent of involvement of organ systems (e.g., kidneys). These basic tests can then be followed by evaluation of biomarkers that are indicative of specific diseases. In addition to their value in establishing a diagnosis, laboratory tests can help assess the activity or severity of a rheumatic disease, its prognosis, and the effects of therapy, including drug toxicity.

MARKERS OF INFLAMMATION

For many patients, the initial goal of laboratory testing is to determine the presence of inflammation (Chapter 36). The immediate response to inflammatory stimuli is termed the *acute phase response* and includes a set of proteins produced primarily in the liver in response to cytokines such as interleukin-6 (IL-6), tumor necrosis factor-α (TNF-α), and IL-1.

Although cytokines and chemokines can be measured in some commercial assays,[1] the most common clinical measures of the acute phase response are the C-reactive protein (CRP) level and the erythrocyte sedimentation rate (ESR). CRP levels provide a nonspecific but useful measure of inflammation of any cause, so they must be interpreted carefully in the evaluation of rheumatic diseases, especially when using high-sensitivity assays that can measure very low concentrations of CRP. Since CRP levels can rise and fall quickly, with a half-life of 5 to 7 hours, the level of this protein can provide a useful measure of disease activity and response to treatment.

The ESR is an indirect measure of acute phase reactants such as fibrinogen, whose production is increased in inflammatory states. The ESR has been traditionally determined using manual approaches such as the Westergren method, which measures the rate of fall of red blood cells (RBCs) in anticoagulated blood in a capillary tube over 60 minutes; in this assay, increased levels of proteins in plasma lead to a faster fall of RBCs. Automated methods to calculate the ESR have good correlation with the Westergren method.[2] The ESR is nonspecific and also depends on the age and sex of the person. In addition, a low CRP but high ESR may indicate a paraproteinemia. Since ESR levels can be slower to change than CRP levels, CRP determinations may be superior to assess the effects of treatment in some settings.

Other molecules, such as serum amyloid protein, fibrinogen, and complement, also are markedly increased during the acute phase response. Patients with inflammation frequently exhibit a leukocytosis or thrombocytosis, most likely reflecting the action of cytokines and other mediators such as glucocorticoids. With chronic inflammation, low albumin levels and anemia of chronic disease can also occur. In systemic lupus erythematosus, lymphopenia, thrombocytopenia, and low CRP values often characterize active disease, with the discordance between laboratory and clinical findings a clue to diagnosis.

LABORATORY EVALUATION OF ARTHRITIS AND RELATED DISEASES

One of the most common presentations of rheumatic diseases is pain in and around the joints, collectively called arthralgia or arthritis. The extent of inflammation varies markedly, however, with some forms such as osteoarthritis (Chapter 241) showing only limited evidence of inflammation either locally or systemically.

If inflammatory arthritis is suspected, further testing depends on the type and distribution of joint involvement. If arthritis is present in only one or two joints, joint aspiration to evaluate for infection or crystal-induced disease is typically indicated, especially for acute disease with evidence of severe inflammation such as fever or joint swelling and redness. Measuring the serum uric acid level is usually not helpful in diagnosing acute gout. Blood cultures can provide important information in assessing the presence of joint infection if joint aspiration cannot be performed.

If polyarticular inflammatory arthritis is suspected, laboratory tests often lead to a correct diagnosis. Since rheumatoid arthritis is the most common form of inflammatory polyarthritis in adults, autoantibody tests for it are typically indicated (e.g., rheumatoid factor and antibodies to citrullinated protein antigens).

RHEUMATOID FACTOR

Rheumatoid factor comprises a family of antibody specificities that bind to the immunoglobulin G (IgG) molecule and react with antigenic determinants that are most likely conformational in origin in the Fc portion.[3] IgM rheumatoid factors are the most abundant of these antibodies. Rheumatoid factors occur in approximately 60 to 80% of patients with rheumatoid arthritis (Chapter 243) and represent one criterion for the classification or diagnosis of this disease. Furthermore, high levels of rheumatoid factors are often associated with the presence of joint erosion, joint deformity, and a worse prognosis.

Rheumatoid factors also can occur in individuals with a wide range of autoimmune, inflammatory, and infectious diseases (e.g., bacterial endocarditis [Chapter 61]), as well as in normal individuals, especially as they age. The

ABSTRACT

The laboratory evaluation for the rheumatic diseases involves both nonspecific and specific biomarkers to determine the extent of tissue injury, the presence of inflammation and autoimmunity, and serologic evidence for the diagnosis. Nonspecific markers of inflammation include C-reactive protein and the erythrocyte sedimentation rate. Specific markers differ by disease and include disease-related and disease-specific autoantibodies. Although common in rheumatoid arthritis, a positive rheumatoid factor can occur in other rheumatic and nonrheumatic diseases. More specific markers of rheumatoid arthritis are antibodies to citrullinated protein antigens (ACPAs). Antibodies to nuclear antigens (ANAs), which are a feature of many rheumatic diseases, target nucleic acids, nuclear proteins, and complexes of nucleic acids and proteins. The target antigens of ANAs vary by disease and include cytoplasmic as well as nuclear molecules. The pattern of ANA expression provides information for classification, diagnosis, and activity of systemic lupus erythematosus. ANAs are also present in diseases such as Sjögren syndrome, systemic sclerosis, and the idiopathic inflammatory myopathies. In the antiphospholipid antibody syndrome, antibodies to phospholipids and a protein called β2-glycoprotein1 can promote thrombosis in vivo, although they can inhibit blood clotting in vitro. For immune complex–mediated diseases, including systemic lupus erythematosus, measurement of complement proteins is useful for assessing disease activity. A group of antibodies, known as antineutrophil cytoplasmic antibodies (ANCAs), react with neutrophil proteins such as proteinase-3 and myeloperoxidase and are important markers of vasculitis. Depending on the clinical scenario, laboratory tests can diagnose and stage disease, help assess the risk for progressive disease, monitor the effects of treatment, and potentially identify appropriate therapy.

frequent occurrence of rheumatoid factors in many conditions likely reflects their functional role in innate immune responses and their ability to promote the binding of IgG to antigen by Fc cross-linking. As a result, the finding of a rheumatoid factor alone may be insufficient to establish the diagnosis of rheumatoid arthritis.

ANTIBODIES TO CITRULLINATED PROTEINS

Antibodies to citrullinated proteins (ACPAs) are important biomarkers for the classification and diagnosis of rheumatoid arthritis (Chapter 243). Citrulline is a post-translational modification of the amino acid arginine that results from deimidation. This chemical reaction is catalyzed by the enzyme peptidylarginine deiminase and may occur in the setting of inflammation. Citrullination can affect many different proteins, thereby creating antigenic sites on proteins that include vimentin, enolase, and filaggrin.

Although most ACPA assays detect IgG antibodies, some assays also detect IgA. Results can vary among commercially available assays, thereby making it important to know the performance characteristics of the assay being used.

ACPAs are highly associated with rheumatoid arthritis and represent a criterion in the classification of patients with this disease.[4] Depending on the assay, these antibodies occur in 60 to 70% of patients with rheumatoid arthritis and uncommonly in patients with other forms of inflammatory arthritis. If rheumatoid arthritis is being considered, testing for both rheumatoid factor and ACPA increases the sensitivity for diagnosing rheumatoid arthritis while also providing good specificity.

Tests for antibodies to carbamylated proteins also may provide useful serologic information. Similar to citrullination, carbamylation is a post-translational protein modification.[5] Patients with rheumatoid arthritis may have neither rheumatoid factors nor ACPAs, thereby denoting their condition as seronegative rheumatoid arthritis in distinction to seropositive rheumatoid arthritis, in which both are present. Seronegativity often prompts the search for another diagnosis that can produce similar signs and symptoms as rheumatoid arthritis.

ACPAs can be expressed before the onset of other signs and symptoms of rheumatoid arthritis. In patients who have arthralgias without evidence of synovitis by examination, the presence of ACPAs may predict the development of arthritis. In the future, ACPA testing may also help identify at-risk individuals who are likely to develop rheumatoid arthritis.[6] Indeed, several randomized controlled clinical trials have been designed to prevent future rheumatoid arthritis in ACPA-positive individuals, but an effective preventive therapy has not yet been identified.[A1–A3]

LABORATORY TESTING FOR OTHER CAUSES OF INFLAMMATORY ARTHRITIS

Although rheumatoid arthritis is a common form of inflammatory arthritis, other conditions, such as Sjögren syndrome (Chapter 247), systemic lupus erythematosus (Chapter 245), and vasculitis (Chapter 249), can produce similar joint findings, and are associated with different autoantibody profiles. Other forms of inflammatory arthritis include the spondyloarthropathies (Chapter 244), such as are seen in psoriatic arthritis, ankylosing spondylitis, and arthritis associated with inflammatory bowel disease. For spondyloarthritis, genetic testing for the human leukocyte antigen (HLA) B27 allele is part of classification criteria and can be part of a diagnostic evaluation, although the frequency of HLA B27 varies markedly depending on the racial and ethnic group. Genetic testing may be helpful in evaluating systemic inflammatory diseases such as familial Mediterranean fever (Chapter 240) that can present with arthritis.[7]

Depending on the clinical findings and initial laboratory testing, other studies may help investigate less common diagnostic possibilities. For example, the serum ferritin level can be markedly elevated in adult-onset Still disease, which can present with arthritis. The laboratory evaluation of inflammatory arthritis may also include serologic tests for infections such as Lyme disease (Chapter 296), human immunodeficiency virus (HIV) infection (Chapter 355), hepatitis (Chapters 134 and 135), or other viral infections such as parvovirus (Chapter 342). Because hepatitis C can cause an inflammatory arthritis in association with an elevated rheumatoid factor, testing for this viral infection is often recommended. Older individuals may report pain, stiffness, and arthralgias as manifestations of polymyalgia rheumatica (Chapter 250), a seronegative inflammatory condition whose most notable laboratory finding is an elevated ESR and/or CRP.

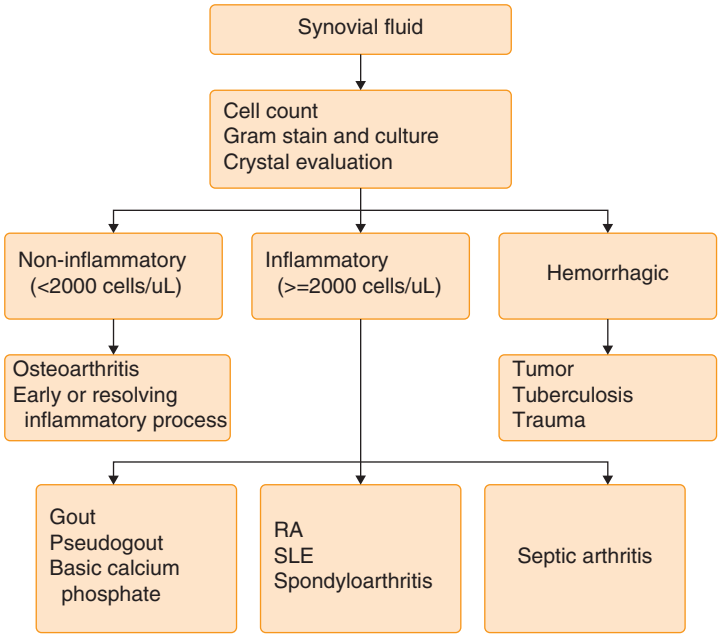

FIGURE 237-1. Algorithm for analysis of joint fluid. Examples of inflammatory arthritis are listed, although many conditions may lead to these results. RA = rheumatoid arthritis; SLE = systemic lupus erythematosus.

JOINT FLUID ANALYSIS

In the evaluation of inflammatory arthritis, analysis of joint fluid (Fig. 237-1) is essential in the setting of acute monoarthritis to investigate the possibility of infection (Chapter 251). In addition, for chronic forms of arthritis, joint fluid should be analyzed if there is uncertainty about the diagnosis or involvement of one joint out of proportion to others. The most informative measures are cell count and differential, crystals, and stains and cultures to evaluate infection.

On the basis of cell counts, joint fluid can be categorized into four main types: noninflammatory, inflammatory, septic, and hemorrhagic. A noninflammatory fluid has fewer than 2000 cells/μL with mononuclear cell predominance. An inflammatory fluid has more than 2000 cells/μL, with 50,000 cells/μL frequently used as the upper limit for this type of fluid. In an inflammatory fluid, polymorphonuclear cells predominate. A septic fluid is an inflammatory fluid in which culture or staining for microorganisms demonstrates infection. Suspicion of infection is especially high for fluids with cell counts greater than 50,000/μL. However, diseases such as rheumatoid arthritis and crystal-induced arthritis can produce cell counts of this magnitude, and an infected fluid can have counts below this level. Hemorrhagic fluids have red cell predominance that can approximate that of blood.

The evaluation for crystals is typically performed by polarization microscopy. With this technique, monosodium urate crystals in gout appear needle shaped and are negatively birefringent. In contrast, calcium pyrophosphate dihydrate crystals in pseudogout are rhomboidal in shape and are weakly positively birefringent. However, some crystals such as basic calcium phosphate, which can cause tendonitis and inflammatory arthritis, can require special microscopy for detection. Infection can coexist with crystal-induced disease, thereby necessitating microbiologic evaluation even when crystals are found. Hemorrhagic fluids can result from infection, although their presence can also indicate malignancy or trauma. In the case of intra-articular fracture, lipids may be found in synovial fluid as a result of release of fats from the bone marrow.

LABORATORY EVALUATION OF SYSTEMIC INFLAMMATORY DISEASE

In addition to arthritis, some rheumatic diseases may cause organ-threatening and life-threatening extra-articular manifestations of the skin, kidney, lung, heart, skeletal muscles, and hematologic and neurologic systems, alone or together, as the predominant issues. Examples include rheumatoid arthritis, systemic lupus erythematosus, Sjögren syndrome, idiopathic inflammatory myopathies (e.g., polymyositis, dermatomyositis), and systemic sclerosis, as well as some forms of vasculitis such as polymyalgia rheumatica/giant cell arteritis, microscopic polyangiitis, and granulomatous polyangiitis. Some rheumatic

diseases are also termed connective tissue diseases because of their pattern of tissue involvement.

ANTINUCLEAR ANTIBODIES

The expression of antibodies to components of the cell nucleus (antinuclear antibodies, or ANAs) is characteristic of connective tissue diseases and is essentially invariable in patients with systemic lupus erythematosus (Chapter 245).[8] ANA positivity is also seen in a high proportion of patients who have other rheumatic diseases such as Sjögren syndrome and systemic sclerosis (Chapter 246). These antibodies target a host of nuclear macromolecules, including DNA, RNA, and proteins as well as complexes of proteins with nucleic acid. ANAs can be either disease-related or disease-specific, depending on their pattern of expression among various conditions.

Results of ANA testing are reported in terms of the pattern of fluorescence as well as the end-point titer of sera at which fluorescence can be observed. The pattern of binding differs depending on the location of the macromolecular target, although the predominant patterns include homogeneous, rim, nucleolar, and speckled. For some sera, more than one pattern of binding may be observed at different dilutions.

Depending on the laboratory and its practices, if an ANA is positive by an immunofluorescence assay, the results can be confirmed and expanded by subsequent assays to identify antibodies to specific nuclear antigens (e.g., Ro/SSA, La/SSB). The immunofluorescence assay allows detection of antibodies directed to antigens in the cytoplasm as well as the nucleus. As for antibodies to nuclear antigens, antibodies to cytoplasmic antigens are important biomarkers. In systemic lupus erythematosus, antibodies can bind antigens in both locales, and antibodies to ribosomal P proteins in the cytoplasm are a specific marker for systemic lupus erythematosus, even though they are not a classification criterion. For several diseases, including systemic sclerosis and inflammatory muscle disease, target antigens are located in the cytoplasm.

Because the molecular targets of many ANAs to antigens within the nucleus or cytoplasm are now known, testing of individual antibodies by an enzyme-linked immunoassay (ELISA) or multiplex-based approaches allows direct identification of autoantibodies to panels of antigens in either the nucleus or cytoplasm. This approach, however, may fail to detect certain ANAs if the antigens are not included in the panel. As a result, multiplex assays are operationally easier than conventional ANA testing by immunofluorescent staining, but the immunofluorescence assay remains an important laboratory test and can be used adjunctively with a multiplex assay (Fig. 237-2).

A major limitation of ANA assays, and especially ANA testing by immunofluorescence assay, is the frequency of positive reactivity in sera of otherwise healthy individuals or individuals who lack clear-cut evidence of a connective tissue disease. Depending on the methodology as well as the cut-off level or titer used to determine positivity, the sera of as many as 20% of otherwise healthy individuals express reactivity in the immunofluorescence assay ANA test. This reactivity, which occurs more commonly in women than in men, may reflect a predisposition to autoimmunity in the absence of other immunopathologic disturbances. This frequency of ANA positivity in the population also appears to be increasing. Because ANA testing is often performed to evaluate nonspecific complaints such as arthralgias, fatigue, and fever, a positive test must be interpreted with caution and not used as evidence of a connective tissue disease in the absence of other clinical or laboratory findings. In the setting of ANA positivity, the presence of antibodies that produce a dense, fine speckled pattern may indicate that the ANA positivity is not associated with an autoimmune disease. These antibodies bind to a protein called lens epithelium-derived growth factor and are denoted as anti-DFS70 antibodies.[9]

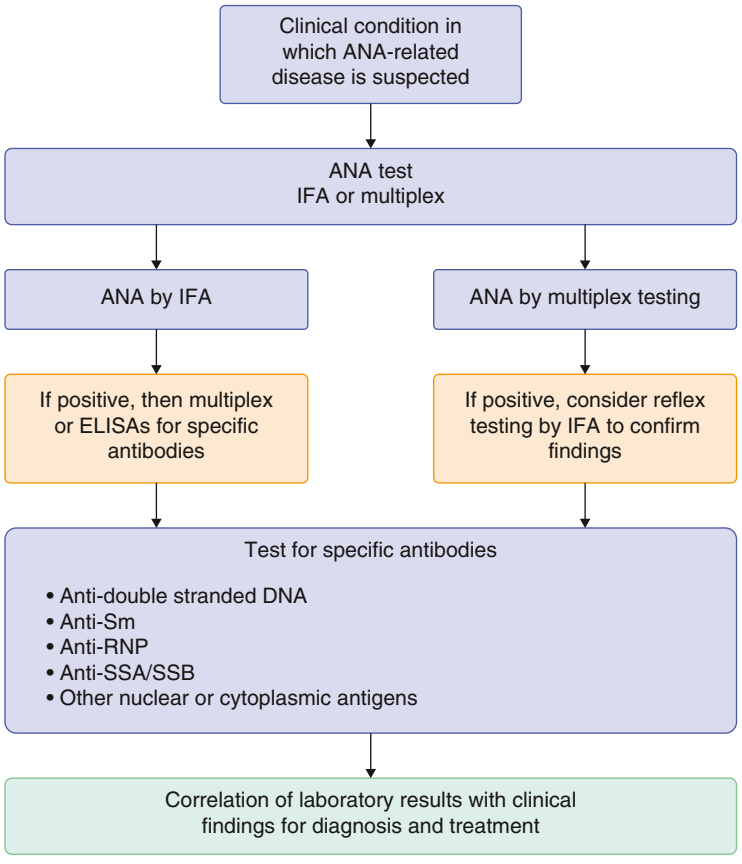

FIGURE 237-2. Approach for antinuclear antibodies (ANAs) testing. The approach to ANA testing may depend on the practices of the local laboratory. ANA testing by immunofluorescence assay or multiplex may be falsely negative owing to methodologic issues, cut-off levels, and/or the antigens included in the assay. If negative, testing using another platform or assay format may be indicated depending on the clinical scenario. Other autoimmune diseases, including idiopathic inflammatory myopathies, systemic sclerosis, and autoimmune hepatitis, may be ANA-positive; for these conditions, further evaluation may include additional testing (e.g., myositis panels). ANA = antinuclear antibody; anti-Sm = anti-Smith antibody; ELISA = enzyme-linked immunoassay; IFA = immunofluorescent assays; RNP = ribonuclear protein; SSA/SSB = anti-Sjögren type A and B.

Antibodies to DNA

Among ANAs associated with rheumatic diseases, antibodies to DNA (anti-DNA) are a highly specific marker for systemic lupus erythematosus and represent a criterion in the classification of patients with this condition. Anti-DNA antibodies also provide a measure of disease activity and response to treatment (Chapter 245).[10] These antibodies bind sites on both single-stranded (ss) and double-stranded (ds) DNA; anti-dsDNA antibodies, however, are more specific for systemic lupus erythematosus and therefore are routinely measured. Although these antibodies can bind free DNA, DNA in the cell occurs in association with histones to form a structure called the *nucleosome*, with DNA wrapped around a histone core. Anti-DNA may therefore be considered a subset of antibodies to nucleosomes or chromatin, with nucleosomes probably serving as the driving antigen for this response

The association of anti-DNA antibodies with disease activity appears strongest with glomerulonephritis, most likely because of the role of DNA–anti-DNA immune complexes in lupus renal disease (Chapter 245). The association of anti-DNA antibodies with other disease manifestations is less certain, thereby limiting the use of this marker as a measure of overall disease activity. The presence of anti-DNA also may be important in assessing the likelihood of response to therapies such as belimumab, which is indicated for the treatment of patients with active autoantibody-positive disease, as evidenced by the presence of either anti-DNA antibodies or a positive ANA.

Anti-DNA antibody assays vary with regard to the spectrum of anti-DNA antibodies detected, and results between assays may not correlate. Nevertheless, for each assay, the dynamic range for testing is large. With treatment and disease quiescence, anti-DNA antibodies may essentially disappear; with flare, levels may increase dramatically. In systemic lupus erythematosus, this property distinguishes anti-DNA antibodies from other ANAs, whose levels tend to be more consistent over time.

Other Antinuclear Antibodies

A number of autoantibodies are associated with a spectrum of rheumatic diseases (Table 237-1). Anti-Sm and anti-RNP antibodies are related antibodies that commonly occur together in the sera of patients with systemic lupus erythematosus, a phenomenon called *linkage*. These antibodies bind proteins on subcellular particles called *snRNPs* (small nuclear ribonucleoproteins) that are composed of a set of proteins and uridine-rich RNAs. Anti-Sm and anti-RNP antibodies differ in protein specificity and in the ability to cause immunoprecipitation of the bound RNA molecules. Anti-Sm antibodies are highly specific for SLE and represent a serologic marker for disease classification.

TABLE 237-1 SELECTED AUTOANTIBODIES IN RHEUMATIC DISEASES

RHEUMATIC DISEASE	AUTOANTIBODIES*
Rheumatoid arthritis (Chapter 243)	*ACPA (including anti-CCP) and rheumatoid factor*; ANA can be positive
SLE (Chapter 245)	*ANA, anti-dsDNA, anti-Sm*, antihistone, anti-Ro (SSA), anti-La (SSB), anti–ribosomal P and anti-RNP. *Antiphospholipid antibodies*
Drug-induced SLE (Chapter 245)	ANA and antihistone; in addition, anti-dsDNA, anti-Ro (SSA) may be present in some drug-induced autoimmune syndromes†
Antiphospholipid antibody syndrome (Chapter 160)	*Anticardiolipin antibody (IgG, IgM, and IgA), anti-beta-2-glycoprotein I antibody (IgG, IgM, and IgA)*‡
Sjögren syndrome (Chapter 247)	ANA, *anti-Ro (SSA), anti-La (SSB)* and rheumatoid factor
Idiopathic inflammatory myopathies (polymyositis, dermatomyositis; Chapter 248)	Myositis-specific autoantibodies include *anti–Jo-1*, anti-SRP, anti–Mi-2, anti-MDA5, anti-TIF1 gamma and alpha and anti-HBGCR. Myositis-associated antibodies include anti-Ro (SSA), anti-La (SSB) and anti-RNP
ANCA-associated vasculitis (Chapter 249)	*ANCA by immunofluorescence; PR3-ANCA, MPO-ANCA*
Mixed connective tissue disease (Chapter 246)	ANA and *anti-RNP*
Systemic sclerosis (Chapter 246)	ANA, *anticentromere, anti–SCL-70* and *anti-RNA polymerase III*

*Autoantibodies listed in italics indicate that these autoantibodies are included in established diagnostic and/or classification criteria.

†These tests may also be abnormal in idiopathic systemic lupus erythematosus. In addition, in some drug-induced autoimmune syndromes there can be broader autoantibody positivity (e.g., ANA and ANCA positivity in antithyroid drug-related autoimmune syndromes).

‡Functional tests include activated partial thromboplastin time and dilute Russell viper venom time.

ACPA = antibody to citrullinated protein/peptide antigen; ANA = antinuclear antibody; ANCA = antineutrophil cytoplasmic antibody; anti-CCP = anti–cyclic citrullinated peptide; anti-dsDNA = anti–double-stranded DNA; anti-Sm = anti-Smith antibody; HMGCR = 3-hydroxy-3-methylglutaryl coenzyme A reductase; Jo-1 = histidyl tRNA synthase; MDA5 = melanoma differentiation-associated gene 5; MPO = myeloperoxidase; PR3 = proteinase 3; RNP = ribonucleoprotein; ScL-70 = topoisomerase I; SLE = systemic lupus erythematosus; SRP = signal recognition particle; SSA/B = Sjögren-associated antigen A or B; TIF = transcriptional intermediary factor.

In contrast, anti-RNP antibodies are considered disease-related autoantibodies because they can appear in the sera of patients with other clinical diseases.[11] In the absence of anti-Sm, anti-RNP antibodies may characterize patients with overlap syndromes, including a specific entity termed mixed connective tissue disease (Chapter 246). Antibodies to Sm and RNP are also denoted as antibodies to RNA-binding proteins (RBPs). Along with other anti-RBPs, anti-Sm and anti-RNP are present in a material known as extractable nuclear antigen (ENA). ENA is a saline extract of tissue and contains antigens such as Sm, RNP, Ro, La, and Jo1. Some laboratories offer a test called an ENA panel to allow assay of this group of antibodies by various formats.

Antibodies to DNA as well as RNA-binding proteins such as Sm and RNP may contribute to overall immune dysregulation in patients with autoimmune disease because of their formation of immune complexes containing DNA or RNA. These complexes can stimulate the production of type 1 interferon by triggering both TLR and non-TLR nucleic acid sensors as well as other cellular receptors (e.g., Fc receptors). Because immunoassays of interferon are limited, the presence of interferon is demonstrated most clearly in a pattern of gene transcript expression known as the interferon signature in peripheral blood cells. Although not yet widely used clinically, transcriptomic assays are commonly performed in studies on mechanisms of disease and of responses to treatment.[12]

Anti-Ro and anti-La antibodies (or anti–SSA and anti–SSB), another set of linked ANAs, are directed to protein-RNA complexes that are involved in cellular metabolism of RNA.[13] Two forms of Ro exist. Ro60 is an RNA-protein complex, whereas Ro52 is a protein known as TRIM22. Anti-Ro and anti-La are expressed more widely in patients with connective tissue disease and appear in the sera of patients with systemic lupus erythematosus, rheumatoid arthritis, and Sjögren syndrome. Assessment of these antibodies is important because of their association with neonatal lupus syndrome, which results from the transplacental passage of antibodies and causes congenital heart block as well as rash in the neonate.

Although both Sm/RNP and Ro/La are complexes of proteins and RNA, these antibodies appear to be expressed by different patient subsets, thereby suggesting distinct mechanisms of induction and clinical associations. In systemic lupus erythematosus, anti-RBPs are expressed independently of anti-DNA.

ANAs are directed to ubiquitous antigens but nevertheless can be associated with specific clinical manifestations. These associations include anti–ribosomal P antibodies with central nervous systemic involvement in systemic lupus erythematosus. In addition, antibodies associated with manifestations of systemic sclerosis include anti-DNA topoisomerase 1 (anti–SCL-70) with diffuse disease; antibodies to centromeres with limited systemic sclerosis (calcinosis, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia); and antibodies to histidyl transfer RNA synthetase (anti–Jo-1) with interstitial lung disease (Chapter 246).[14] In addition, in systemic sclerosis, anti-RNA polymerase III can be associated with an increased risk for underlying malignancy.[15]

In idiopathic inflammatory myopathies (Chapter 248), the presence of certain autoantibodies may be associated with particular patterns of disease.[16] As a group, antibodies to tRNA synthetases are associated with characteristic clinical findings that have been termed anti-synthetase syndrome. Antibodies to melanoma differentiation-associated gene-5 (MDA5) are associated with a more severe course of myositis with interstitial lung disease, whereas antibodies to the enzyme 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase and signal recognition particle (SRP) are associated with necrotizing myositis. In addition, antibody to transcriptional intermediary factor 1 gamma (TIF1gamma) is associated with hyperkeratotic papules on the skin, as well as increased risk for underlying malignancy.

Antibodies to Phospholipids

Originally defined by their effects on in vitro clotting tests, antibodies to phospholipids are associated with in vivo thrombosis and have been termed *lupus anticoagulants*.[17] Patients with these antibodies display a clinical condition termed antiphospholipid antibody syndrome characterized by arterial or venous thrombosis, thrombocytopenia, and first-trimester spontaneous abortions (Chapter 67). This syndrome may occur by itself or in the context of systemic lupus erythematosus. Although venous and arterial clots are a hallmark of antiphospholipid syndrome, accelerated atherosclerosis, valve disease, and alveolar hemorrhage are also associated with this condition.

The laboratory evaluation of antiphospholipid syndrome involves specific assays of antibodies to phospholipids and certain proteins, as well as functional assays of clotting. Because expression of these antibodies may vary over time, testing must be performed on more than one occasion at least 6 weeks apart. Furthermore, the results of immunochemical and functional assays may not be congruent, likely related to the heterogeneity of antibodies.[18]

The serology of antibodies to phospholipids is complicated because it is related to the nature of the antigenic targets as well as heterogeneity among patients. These antigens include phospholipids such as cardiolipin. Cardiolipin, however, can bind to the protein β_2-glycoprotein 1, which is also a target for antibodies in this condition. Serologic evaluation thus involves assays with a complex of cardiolipin and β_2-glycoprotein 1 as well as β_2-glycoprotein 1 in an ELISA format using reagents to measure IgG, IgA, and IgM, although the association of antibodies with thrombosis appears strongest with IgG antibodies. In interpreting these assays, it is important to know the cut-off values used to define positivity.

Functional assays for lupus anticoagulants involve tests directed at inhibition of in vitro clotting (e.g., activated partial thromboplastin time, dilute Russell viper venom time), recognizing the discordance between in vivo thrombosis and in vitro anticoagulation. Functional assays to detect lupus anticoagulants involve a mixing step in which patient plasma is mixed with normal plasma to determine the presence of an inhibitor (i.e., an antibody) as opposed to a deficiency state. Importantly, the use and interpretations of these assays may need to be modified in individuals who are taking anticoagulants.

Complement

Assessment of the complement system can provide valuable information on the activity of diseases in which immune complex deposition can promote

inflammation and tissue injury (Chapter 37).[19] In the setting of systemic lupus erythematosus, certain forms of vasculitis, glomerulonephritis, and atypical hemolytic uremic syndrome, complement is activated by immune complexes. Activation of the complement system can be measured in terms of the total complement level, levels of C3 and C4, and levels of complement fragments bound to RBCs.

Low levels of complement proteins may reflect their consumption but also can be caused by inherited complement deficiencies or copy number variations. Genetic deficiency of C1q, for example, is highly associated with systemic lupus erythematosus. In addition, proteins of the complement system are also acute phase reactants and can increase with inflammation. With the advent of complement-directed therapies for diseases (e.g., atypical hemolytic-uremic syndrome), as well as commercial assays that can use patterns of complement activation products to identify specific disease, complement testing may become more common in clinical care.

Antineutrophil Cytoplasmic Antibodies

Antineutrophil cytoplasmic antibodies (ANCAs) are autoantibodies that react to antigens in the neutrophil and occur prominently in patients with certain forms of necrotizing vasculitis and/or rapidly progressive glomerulonephritis (Chapter 107). Reflecting the serology, conditions have been called ANCA-associated vasculitis (AAV; Chapter 249).

Two main forms of ANCAs have been distinguished on the basis of the target antigens and pattern of immunofluorescence staining of fixed neutrophils: PR3-ANCA (C-ANCA), which reacts with proteinase-3 (PR3), and MPO-ANCA (P-ANCA), which reacts with myeloperoxidase (MPO). By immunofluorescence, PR3-ANCA shows staining in the cytoplasm; staining by MPO-ANCA localizes in the perinuclear area. ANCAs can occur in conditions other than vasculitis, including an immune syndrome resulting from the drug levamisole, which is used as an adulterant in cocaine. In addition, ANCAs can be present in conditions such as inflammatory bowel disease (Chapter 127), autoimmune liver disease (Chapter 135), and systemic lupus erythematosus (Chapter 245); however, the specific antigens targeted by ANCAs in these diseases are not well characterized.

In the evaluation of severe, multisystem inflammatory disease that often involves the renal and pulmonary systems, ANCA testing is important to evaluate diagnostic possibilities.[20] ANCAs occur in association with varying clinical manifestations in patients with ANCA-associated vasculitis and help define patterns of histopathology as well as organ system involvement. PR3-ANCA occurs commonly in patients with granulomatosis with polyangiitis (GPA), as well as eosinophilic granulomatosis with polyangiitis (EGPA, formerly called Churg-Strauss disease). MPO-ANCA marks the course of vasculitis caused by microscopic polyangiitis. Despite overlap between serology and clinical features, PR3-ANCA occurs commonly in patients with upper airway disease, whereas MPO-ANCA occurs commonly in patients with rapidly progressive renal disease (Chapter 249).

As with ANA testing, ANCA testing can be done in a reflex approach in which immunofluorescence assay testing is performed first. If an ANCA is identified, then additional testing (e.g., ELISA) is done to determine whether anti-PR3 or anti-MPO is present. One approach to optimize sensitivity and specificity of ANCA testing is to test ANCA by IFA as well as ELISA for PR3-ANCA and MPO-ANCA. This allows for identification of possible non-PR3/MPO reactivities associated with an ANCA.

In patients with ANCA-associated glomerulonephritis (Chapters 107 and 249), the kidney lacks evidence of immune deposits, as indicated by the lack of staining for immunoglobulins or complement. Kidney disease of this kind is termed *pauci-immune glomerulonephritis*. Although ANCA testing is useful in initial diagnosis, its role for assessing disease activity is less certain. Occasionally, in patients who are critically ill and cannot tolerate a lung or kidney biopsy, the presence of an ANCA can provide preliminary evidence for diagnosis and allow the initiation of immunosuppressive therapy. ANCA testing is also useful for assessing the likelihood for relapse because patients who express PR3-ANCA appear at risk for recurrent disease.

ANCA-associated conditions can present as a pulmonary-renal syndrome because of the prominent involvement of these organs. Goodpasture syndrome is another example of a pulmonary-renal syndrome whose presence can be assessed by testing for antibodies to the glomerular basement membrane by an immunofluorescent method using tissue slices.

CRYOGLOBULINS

Cryoglobulins are serum immunoglobulins that precipitate in the cold and can mediate disease through tissue deposition.[21] A finding suggesting cryoglobulinemia is an elevation of rheumatoid factor with a concomitant low C4 and normal C3 level. The presence of a cryoglobulin can be detected by allowing blood, collected warm, to remain cool at 2° to 4° C for 1 or more days. After centrifugation, the amount of cryoprecipitate is measured and expressed as a cryocrit. Prior to the actual incubation in the cold, it is important that the blood remain at a temperature of 37° C.

Subsequent analysis of the cryoprecipitate by immunochemical assays allows determination of its components. Cryoglobulins can be classified into three main types on the basis of their composition: (1) single, or type I, which typically are seen in lymphoproliferative disorders such as multiple myeloma (Chapter 173); (2) mixed, type II, which can be seen in lymphoproliferative disorders as well as rheumatic diseases and in infections such as hepatitis C (Chapters 134 and 135); and (3) mixed, type III, which is associated with rheumatic diseases as well as infection, including hepatitis C. A type I cryoglobulin consists of only a monoclonal immunoglobulin that precipitates in the cold. A mixed-type cryoglobulin contains rheumatoid factors bound to polyclonal IgG to form an immune complex. In type II cryoglobulins, the IgM rheumatoid factor is monoclonal, whereas the IgM rheumatoid factor is polyclonal in type III.

The clinical findings associated with cryoglobulinemia often mimic those of primary rheumatic diseases; in addition, rheumatic diseases, especially systemic lupus erythematosus and Sjögren syndrome, may lead to cryoglobulinemia. Individuals with mixed cryoglobulins can present with a wide range of signs and symptoms resulting from cryoglobulin-mediated vasculitis, including purpura (a sign of leukocytoclastic vasculitis), weakness, arthritis, neuropathy, and nephropathy. As in the case of other connective tissue diseases and systemic inflammatory diseases, the evaluation of patients with essential mixed cryoglobulinemia demands attention to the entire patient and the impact of disease on multiple organs.

LABORATORY TESTING TO MANAGE THERAPY

Laboratory testing is increasing by being used to guide therapy. Standard tests such as complete blood counts and hepatic function panels can monitor the potential toxicity of medications. Testing can also evaluate an individual's ability to metabolize a drug (e.g., thiopurine methyltransferase levels for use of azathioprine) or predict toxicity (e.g., the HLA-B*58:01 gene is associated with increased risk for adverse reactions from allopurinol, and p-450 gene polymorphisms are associated with toxicity from nonsteroidal anti-inflammatory agents).[22] Drug levels of many agents (e.g., hydroxychloroquine and methotrexate) are now available, and some biologic agents have assays to detect antidrug antibodies that can help determine if immune responses to a drug are reducing its efficacy. An emerging area is the use of laboratory testing, which may include blood or tissue-based tests such as synovial or renal biopsy, to identify the optimal therapy for a specific patient.[23,24]

238 IMAGING STUDIES IN THE RHEUMATIC DISEASES

RONALD S. ADLER

Advanced rheumatic disorders usually can be well characterized by conventional imaging. However, the development of new therapeutic alternatives for the inflammatory arthritides, so-called disease-modifying antirheumatic drugs (DMARDs), and chondroprotective strategies for osteoarthrosis require methods to diagnose these diseases at an earlier stage, characterize the degree of inflammation, and provide a useful metric to assess therapeutic response (Chapters 28 and 29). Indeed, it has become necessary to assess for possible joint and soft tissue abnormalities before irreversible tissue damage and when the radiographic findings are not yet abnormal. Fortunately, the requirement to achieve earlier diagnosis has paralleled advances in imaging. Ultrasonography and magnetic resonance imaging (MRI) have largely supplanted conventional radiographic evaluation in the imaging evaluation of patients with suspected rheumatologic disorders and negative radiographs. The term *molecular imaging* has been applied, particularly in the case of MRI and positron emission tomography (PET), inasmuch as these modalities reflect local tissue environment or metabolic activity.[1]

RADIOGRAPHIC EVALUATION

Radiographs are projection images. To detect an abnormality, it may be necessary to view a joint or other structure at a specific angle. For instance, subtle erosions in rheumatoid arthritis (Chapter 243) may be apparent only when viewed tangentially, as opposed to *en face*. Most radiographic evaluations contain at least two orthogonal projections. The addition of an oblique view or other specialized projection may be necessary to address a specific clinical question.

The nature and distribution of joint space narrowing, presence of osteopenia, new bone formation, soft tissue swelling, soft tissue calcification, chondrocalcinosis, presence and nature of erosions, and assessment for joint malalignment may allow a specific diagnosis (Table 238-1), as well as help determine the severity of disease (Fig. 238-1). For instance, the presence of a juxta-articular erosion extending over an adjacent area of slightly hyperdense soft tissue swelling in the setting of normal bone mineralization with maintenance of the adjacent joint space is diagnostic of gout (Chapter 252), in contrast to rheumatoid arthritis. The seronegative arthritides, such as psoriatic arthritis (Chapter 244) and reactive arthritis (Chapter 254), have a characteristic appearance in the small joints of the hand and feet, with a predilection for distal joints, asymmetry, and appositional new bone formation.

Radiographs also provide a direct means for needle localization during percutaneous procedures, predominantly joint injections, aspirations, and some biopsies. These procedures are generally performed guided by imaging in real time (fluoroscopy) using short bursts of low-intensity x-rays enhanced through an image intensifier. Injection of joints under fluoroscopic guidance provides a convenient means to ensure intra-articular deposition of the therapeutic agent or for diagnostic aspiration. Intra-articular location is verified by injection of a small amount of a standard iodinated contrast material. Arthrography using fluoroscopic guidance can be used as a primary diagnostic tool, but this application has largely been replaced by intra-articular injection of contrast followed by computed tomography (CT) or MRI.

For some procedures, CT may be preferable, depending on the location of the abnormality. The principal disadvantages of fluoroscopy relate to the use of ionizing radiation and poor soft tissue contrast. The latter becomes important with needle placement near neurovascular structures that may be potentially compromised by poor needle position. CT allows greater control over needle placement at the cost of greater levels of radiation exposure. Ultrasonography has replaced fluoroscopy and CT for a large number of percutaneous procedures. MRI provides another method to guide a variety of procedures without the necessity of ionizing radiation. These options will be discussed in greater detail later.

COMPUTED TOMOGRAPHY

CT provides a two-dimensional map of tissue attenuation obtained from external x-ray source(s) located on a rotating gantry, whose radiation is detected by

TABLE 238-1 DISTINGUISHING RADIOGRAPHIC FEATURES OF SEVERAL COMMON RHEUMATIC DISEASES

CONDITION	COMMON SITES	DISTRIBUTION	RADIOGRAPHIC FEATURES
Rheumatoid arthritis	Hands: MCP, PIP; wrists: intercarpal, DRUJ, ulnar styloid; feet: fifth MTP; cervical spine (atlantoaxial, apophyseal)	Bilateral, symmetric, polyarticular	Juxta-articular osteopenia, periarticular swelling, subluxations (e.g., ulnar, volar), uniform joint space loss, erosions (bare areas)
Osteoarthritis (primary)	Hands (DIP), wrists (basal joint, STT), feet (first MTP), hips (superolateral), knees (medial), spine (discs, facet, or apophyseal, uncovertebral)	Symmetric, weight-bearing joints	Normal or increased density, nonuniform joint space loss, subchondral sclerosis, cysts, bone formation (osteophytes) Spine: disc space narrowing, end plate sclerosis, and bone formation
Psoriatic arthritis	Hands (DIP, terminal tufts), feet (IP joints), entheses (calcaneus-plantar, posterior), spine, SI joints	Asymmetric (single ray), polyarticular, segmental (intervertebral, apophyseal)	Normal or increased density, periosteal bone formation, soft tissue swelling, ankylosis (SI joints), thick hyperostosis spine (nonmarginal syndesmophytes), juxta-articular and periarticular erosions
Ankylosing spondylitis	Spine, SI joints, fibrous joints (pubic symphysis), entheses (adductor origin), rhizomelic joints (hips, shoulders)	Symmetric, continuous (may affect entire spine: bamboo spine)	Normal or increased density, erosions (spine: squaring, shining corner) with superimposed bone formation (ankylosis: SI, thin [marginal] syndesmophytes)
Gout	Feet (first MTP), other damaged joints, elbow, knee, hindfoot	Asymmetric, extensor surfaces (elbow), abnormal joints (e.g., osteoarthritic joints)	Normal joint space, normal or increased density, dense soft tissue nodules (tophi), para-articular and subchondral erosions with bone formation along tophi (overhanging edge)
CPPD	Hands (second, third MCP), wrists (radiocarpal, TFC), knees (lateral compartment and patella-femoral, menisci)	Symmetric, fibrocartilaginous joints	Normal or increased density, hypertrophic bone formation, subchondral or periarticular cysts, chondrocalcinosis (hyaline, fibrocartilage), periarticular, peritendinous, periligamentous calcification
Infection	Any joint (pyogenic, TB)	Monoarticular (mostly), any joint	Pyogenic: osteopenia (days), joint space widened (early), joint space loss (rapid development), soft tissue swelling, erosions—both sides of joint, sequestra, periostitis TB: joint space and mineralization may be preserved, juxta-articular erosions Spine: disc space loss and end plate erosion

CPPD = calcium pyrophosphate deposition disease; DIP = distal interphalangeal; DRUJ = distal radial ulnar joint; IP = interphalangeal; MCP = metacarpophalangeal; MTP = metatarsophalangeal; PIP = proximal interphalangeal; SI = sacroiliac; STT = scaphotrapeziotrapezoid; TB = tuberculosis; TFC = triangular fibrocartilage.

ABSTRACT

Historically, rheumatic disorders have been well characterized by conventional imaging. Radiographic evaluation has been sufficient both to characterize these conditions and to provide a relatively small number of differential diagnostic possibilities regarding the specific disease. The development of new therapeutic alternatives for the inflammatory arthritides, the so-called disease-modifying antirheumatic drugs, and chondroprotective strategies in the case of osteoarthrosis require methods to diagnose these diseases at an earlier stage, characterize the degree of inflammation, and provide a useful metric to assess therapeutic response. Fortunately, the requirement to achieve earlier diagnosis has paralleled advances in imaging. Ultrasound and magnetic resonance imaging have largely supplanted conventional radiographic evaluation in much of the imaging work-up of patients with suspected rheumatologic disorders. Radiographic evaluation, computed tomography, magnetic resonance imaging, ultrasound, and nuclear medicine collectively provide important information in evaluating patients with these disorders and are briefly reviewed.

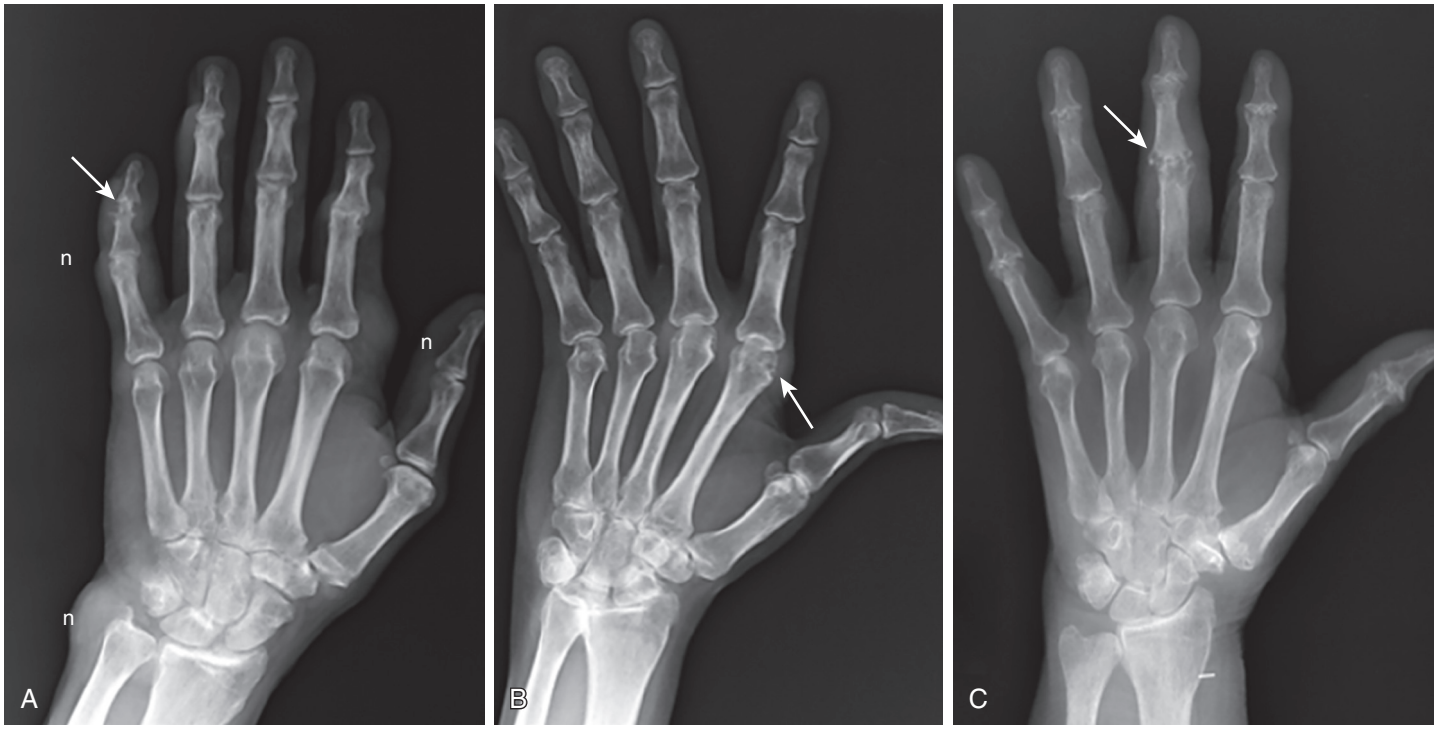

FIGURE 238-1. Three hands with different diagnoses. A, Gout. Radiograph of the left hand showing multiple dense soft tissue nodules (n) with multiple small erosions affecting the ulnar styloid, triquetrum, and fifth ray. A large erosion (*arrow*) at the fifth distal interphalangeal (DIP) joint demonstrates bone formation extending circumferentially about the adjacent tophaceous deposit typical of an overhanging edge. Bone mineralization and joint spaces are preserved. **B,** Rheumatoid arthritis (RA). There is ulnar deviation of the second through fifth metacarpophalangeal (MCP) joints with uniform joint space loss involving the MCP joints and the carpus. There is mild ulnar translation of the carpus. The DIP joints are spared. Periarticular demineralization is present with small erosions along the radiovolar aspect of the second MCP joint (*arrow*). **C,** Osteoarthrosis. Soft tissue swelling affecting the third digit with joint space narrowing and bone production affecting the DIP joints, third and fifth proximal interphalangeal (PIP) joints, basal joint of the thumb, and scaphotrapeziotrapezoid joint. There are subchondral cystic changes at the third PIP joint having an erosive character (*arrow*). Mineralization is preserved, and radiocarpal as well as MCP joint spaces are preserved.

a series of detectors opposite the source. The current generation of CT scanners employs multiple detectors (16, 32, 64, and so on), allowing rapid image acquisition that can be displayed in a single plane in real time (CT-fluoroscopy) or as extremely thin-section contiguous or overlapping acquisitions in the axial plane. The acquired images can be reconstructed in multiple planes with equivalent (isotropic) resolution elements (voxels) or as a three-dimensional rendering. Some scanners use dual energy sources to take advantage of differences in the attenuation characteristics of various tissues at different energies (Fig. 238-2), thereby enabling a definitive diagnosis with greater sensitivity in depicting tophaceous deposits even in anatomic locations not conducive to radiographs or ultrasound.

CT allows the best assessment of trabecular and cortical bone, providing an excellent means to assess fractures and erosions, the presence of new bone formation (e.g., fracture callus), and degenerative or inflammatory arthritis.[2] Soft tissue mineralization can likewise be well characterized, providing important information as to its etiology. Joints that are difficult to assess on radiographs, including the sacroiliac, temporomandibular, wrist, and sternoclavicular joints, are well seen on CT (Fig. 238-3).

CT generally has poor soft tissue contrast. Nevertheless, it is still very useful in performing a number of guided procedures because of its tomographic nature and rapid image acquisition capability. Improved soft tissue contrast can be obtained with use of iodinated contrast material. A number of soft tissue tumors, inflammatory synovitis, and infectious processes display pathologic enhancement after contrast administration. CT can likewise be used to produce angiographic displays (CTA) when used in combination with contrast, thereby providing exquisite detail of central and peripheral vascular disease, including in patients with suspected vasculitis. These agents are typically administered intravenously following well-defined enhancement characteristics. Likewise, contrast agents may be used to improve intra-articular imaging (CT arthrography) for the assessment of internal derangement in the postoperative shoulder, knee, and so on and in patients who are unable to undergo MRI (e.g., patients who have claustrophobia, aneurysm clips, or some cardiac pacemakers). Imaging of cartilage and soft tissue abnormalities usually depends on pathologic inhibition of contrast material, indicative of degeneration or tearing. A limitation of this approach resides in the fact that some abnormalities may remain occult. An example is the inability to detect a bursal-sided rotator cuff tear after shoulder CT arthrography.

The radiation dose from CT can be high, especially when using the newer scanners. Iterative image reconstruction techniques as well as sparse sampling (compressed sensing) may allow for compensatory dose reduction. Intravenous (IV) use of iodinated contrast agents is contraindicated in patients with impaired renal function or a history of allergic reaction. Nonionic agents can diminish the associated risks but still should be used with caution.

ULTRASONOGRAPHY

Ultrasound imaging takes advantage of the near-uniform speed of sound and predictable attenuation characteristics of sound propagation in soft tissue. Rapid acquisition and processing enable ultrasound to be performed in real time (approximately 30 frames per second). Ultrasonography also can evaluate blood flow, from which estimates of flow velocity can be obtained through the Doppler equation (Chapter 43).

Ultrasonography's appeal in patients with rheumatic disorders includes the absence of ionizing radiation, as well as the fact that it is real-time, inexpensive, relatively portable, and well tolerated. The traditional uses of ultrasound to detect a Baker cyst in the knee[3] or a joint effusion have expanded with the development of a new class of compact and portable ultrasound units that have excellent image quality.

The current generation of ultrasound scanners enables examination of the small joints of the hands and feet, allowing early detection of synovitis (Fig. 238-4).[4] The displacement of the joint capsule by hypoechoic (dark) soft tissue that displays vascularity on Doppler imaging or is incompressible with direct pressure by the transducer is characteristic, thereby allowing differentiation of synovitis from an effusion. In addition to the detection of synovitis, ultrasonography is more sensitive than conventional radiographs for the detection of erosions. Erosions appear as discrete irregular discontinuities in the normally smooth hyperechoic (bright), reflecting cortical surfaces, often seen in continuity with adjacent inflammatory soft tissue.

The level of vascularity on color flow imaging correlates with clinical and biochemical parameters and can reflect active inflammation.[5] When standard ultrasonography is combined with color flow imaging, the activity of the synovitis can be estimated. Ultrasound contrast agents can depict capillary flow, thereby resulting in significantly improved sensitivity for detecting synovial inflammation. These microbubble agents are encased in a lipid or polysaccharide shell that can be instilled as either bolus or constant infusion, with the

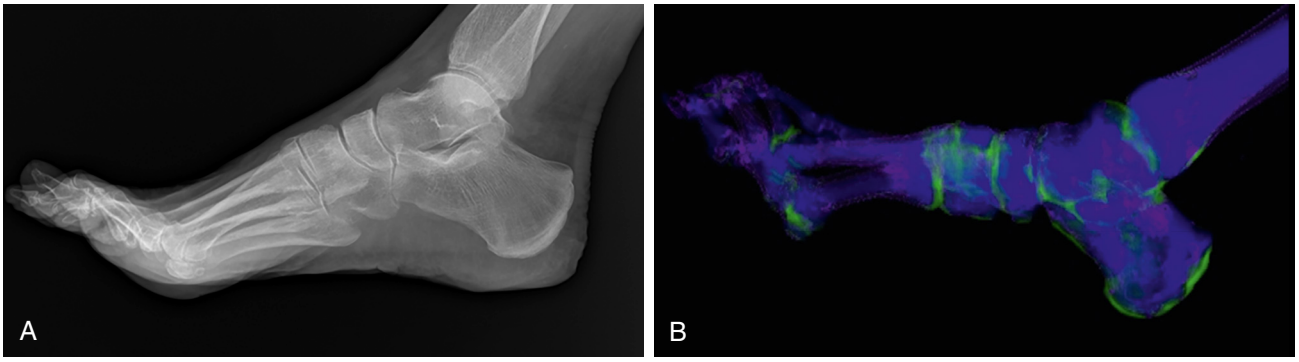

FIGURE 238-2. **Male age 62 years with right foot pain and clinically suspected gout. A,** Lateral radiograph of the right shows mild osteopenia without other evident abnormalities. **B,** Three-dimensional rendered image obtained from a dual energy acquisition, with blue representing normal cancellous and/or cortical bone and green designating tophaceous deposits scattered throughout the foot.

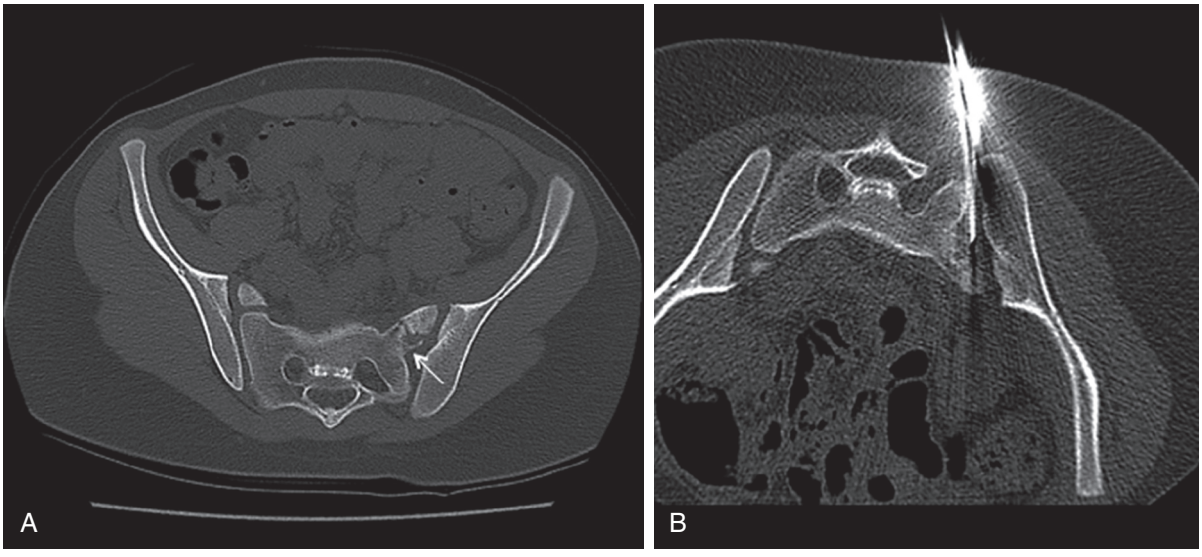

FIGURE 238-3. **Infectious sacroiliitis in a 12-year-old boy with a 2-week history of back and left hip pain. A,** Axial computed tomography (CT) image of the pelvis at the level of the sacroiliac (SI) joints photographed using window settings optimized for bone detail. There is clear asymmetry in the two SI joints, with the left appearing more irregular. The cortical margins of the left sacral ala are less distinct, and there is an isolated bone fragment (*arrow*) surrounded by soft tissue suspicious for a sequestrum. **B,** CT-guided aspiration of the left SI joint confirmed an infectious origin.

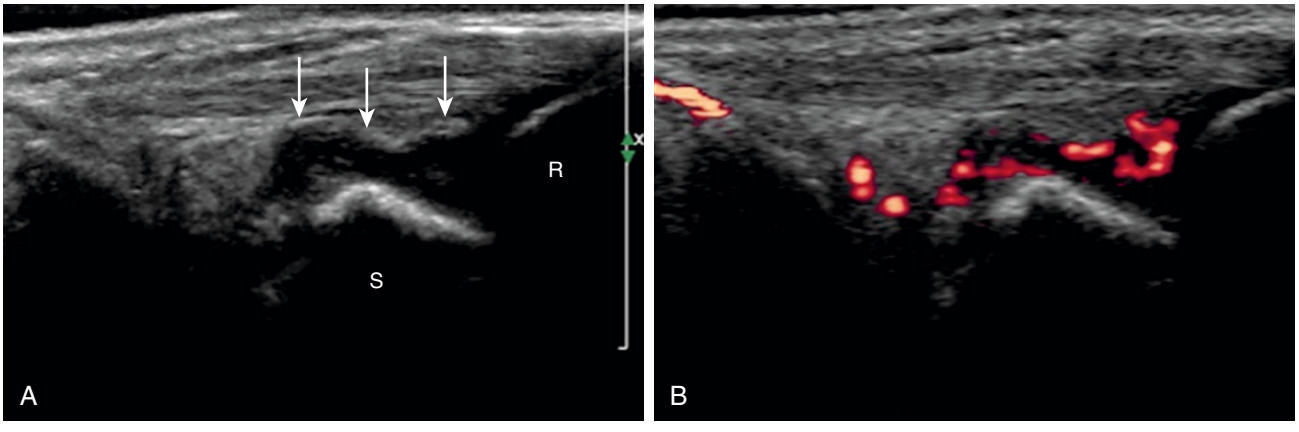

FIGURE 238-4. **Synovitis on ultrasound in a female patient with normal hand radiographs. A,** Gray-scale ultrasound image obtained along the dorsal aspect of the radioscaphoid joint shows hypoechoic soft tissue (*arrows*) distending the dorsal recess. The cortical margins of the scaphoid (S) and radius (R) appear as bright reflectors on ultrasound. **B,** Power Doppler image depicts the marked vascularity (red hues) of the soft tissue illustrating the level of disease activity.

shell being metabolized in the liver and the gas exhaled in the lungs. Although such agents have received U.S. Food and Drug Administration approval for cardiovascular and abdominal applications at this time, they can be used only off-label for the assessment of synovitis.

Articular cartilage and fibrocartilage have characteristic appearances on ultrasonography. Whereas the former appears as a thin hypoechoic band paralleling the articular surface, fibrocartilage appears hyperechoic. Chondrocalcinosis appears as discrete hyperechoic foci within the substance of the cartilage, in which case its presence is suggestive of calcium pyrophosphate deposition disease. Calcification along the margin of the articular cartilage gives rise to the double-contour sign seen in gout.

Tendons and muscles have characteristic appearances on ultrasonography. The presence of tendinosis, tendon tears, muscle edema or inflammation, atrophy, and tears can be diagnosed.[6] Ultrasonography is very sensitive,

although not specific, for the detection of small amounts of calcification or ossification. It is an excellent method to assess for calcific peritendinitis or periarthritis and to provide guidance for treatment. Abnormal fluid distention of synovial-lined structures can be assessed and treated under ultrasound guidance. Ultrasonography is an excellent modality to provide image guidance for therapeutic aspiration and injection of small and large joints, tendon sheaths, and cysts (e.g., bursae, ganglion, paralabral cysts, hematomas, abscesses) (Fig. 238-5). The real-time capability of ultrasonography is useful to demonstrate the presence of subluxations, to evaluate painful snapping, to document the distribution of injected material, and to assess adhesions. Ultrasonography is considered the method of choice to detect foreign bodies.

Newer ultrasound techniques provide a map of soft tissue mechanical properties, also known as ultrasound elastography (USE). These techniques fall into two categories, compression-based or shear-wave elastography. The former employs speckle tracking to estimate local tissue strain following minimal external compression of the tissue being examined, thereby producing a color-encoded strain map or map of tissue hardness. The latter method employs a shear wave produced either by an external source or by the transducer itself, the speed of the shear wave being an indirect measure of local Young modulus; a color-encoded map or quantitative estimate of local shear-wave speed or elastic modulus can be derived. Both techniques provide information regarding alterations of mechanical properties of tendons and muscles in a variety of degenerative, traumatic, and reparative states. For example, fatty infiltration resulting from chronic myopathic disorders produces measurable alterations in local muscle elastic modulus.

Nerves also have a characteristic appearance on ultrasonography. In cross section, a nerve often has a "cluster of grapes" or "honeycomb" appearance, with nerve fascicles appearing hypoechoic and surrounded by hyperechoic internal and external epineural fat. In the long axis, nerves display a characteristic "tram-track" appearance. Ultrasonography is useful in the diagnosis and treatment of carpal tunnel syndrome (Chapter 388)[7] and cubital tunnel syndrome. It is an excellent modality to assess for the presence of post-traumatic or post-surgical and interdigital neuromas and to provide image guidance for treatment, including therapeutic injections, nerve blocks, and ablative therapy.

Although ultrasonography is well suited to the evaluation of superficial structures, it is less well suited to assess deep structures. In some instances, soft tissue contrast can be poor. An inexperienced scanner may find ligaments and tendinous insertions difficult to differentiate from adjacent fibrofatty structures or mistake tendon anisotropy for tendinosis or complex fluid.

MAGNETIC RESONANCE IMAGING

Two tissue-dependent relaxation times, T1 and T2, vary with field strength. T1 (also known as the spin-lattice relaxation) and T2 (or the transverse relaxation time) along with proton density are the principal determinants of signal intensity. An image can emphasize either the T1 or T2 characteristics of the tissue. Different tissues have varying appearances, often based on levels of fat and water content, as reflected by their inherent T1 and T2 relaxation times. On T1-weighted or proton density images, tendon, muscle, fat, marrow, cortical bone, articular, and fibrocartilage have characteristic appearances. Many pathologic states are characterized by increased mobile water or effective T2 lengthening. Examples include soft tissue or marrow edema, inflammatory infiltrates, and neoplasm (Figs. 238-6 and 238-7). Images that emphasize T2 contrast are therefore helpful to display most pathologic states. Selective maps of T2 have been used to characterize the state of articular cartilage in early degenerative disease. Other cartilage-specific properties that relate to water content, glycosaminoglycan (GAG) content, and integrity of collagen architecture can be assessed using T2 and other parametric maps that can be derived from the MR data (Fig. 238-8).

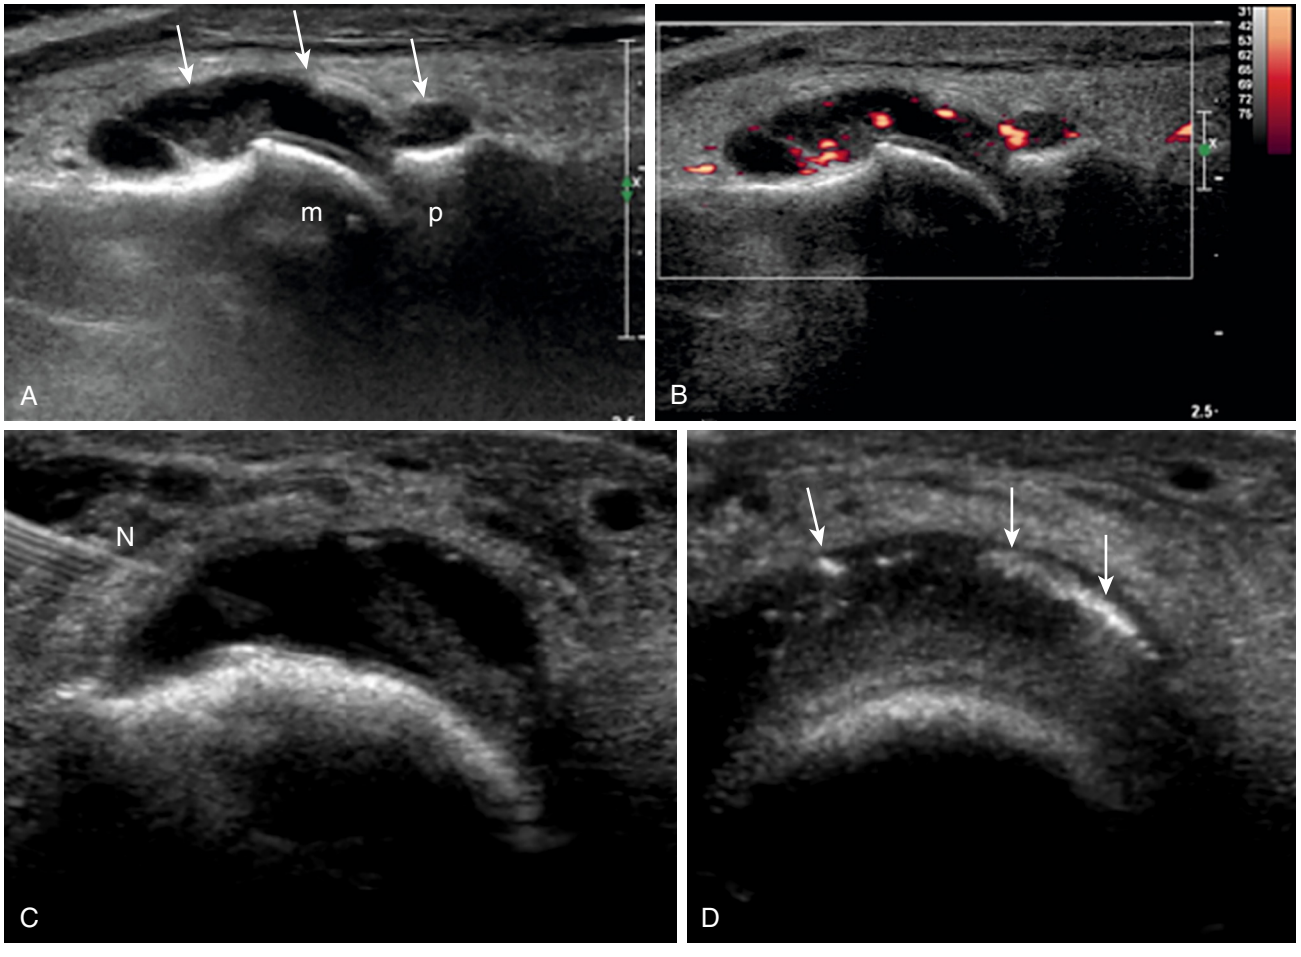

FIGURE 238-5. Ultrasound-guided therapy in the first metatarsophalangeal (MTP) joint of a female patient with pain and swelling. A, Longitudinal gray-scale image of the dorsal recess of the first MTP joint. Fluid and soft tissue distend the joint capsule (*arrows*). The metatarsal (m) and proximal phalanx (p) are labeled. Note that a thin hypoechoic (dark) band parallels the surface of the metatarsal head, corresponding to the overlying articular cartilage. **B,** Increased vascularity (red hues) demonstrated on power Doppler imaging within the dorsal recess reflects the level of disease activity. **C,** Transverse gray-scale ultrasound image shows a needle (N) within the distended dorsal recess from which several drops of synovial fluid were aspirated, followed by therapeutic injection. **D,** Postinjection transverse sonogram depicts low-level echoes (small echogenic foci within dorsal recess) and microbubbles (*arrows*) within the distended joint capsule from injected material. Microbubbles will aggregate along the nondependent portion of the distended joint capsule, whereas injected material tends to settle to the deep portion of the joint.

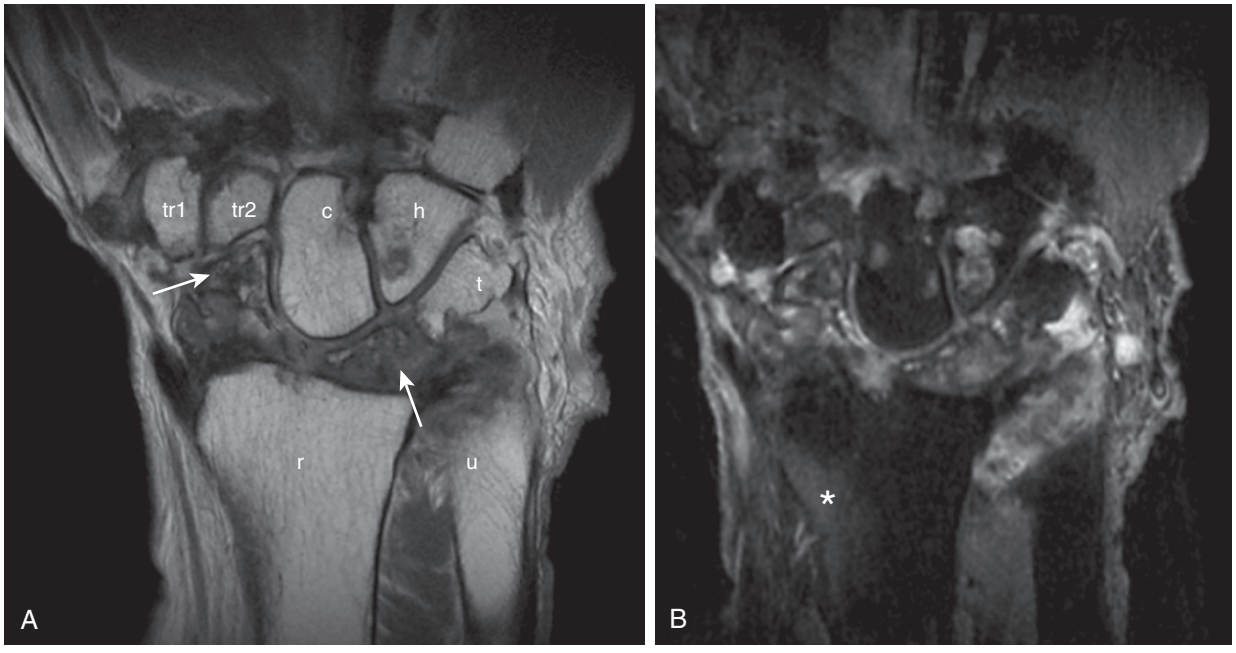

FIGURE 238-6. **Magnetic resonance imaging of the right wrist in a female patient with advanced rheumatoid arthritis. A,** Proton density coronal image shows loss of normally bright marrow signal within the scaphoid and lunate bones (*arrows*). The proximal scaphoid is eroded, and the lunate appears deformed and translocated and volarly tilted (not shown), giving rise to its triangular appearance. The distal ulna (u) is poorly visualized due to a large erosion. Intermediate-intensity material (appears dark gray) within the carpus and distal radioulnar joint is difficult to separate from the distal ulna, lunate, and scaphoid. The triquetrum (t), hamate (h), trapezium (tr1) and trapezoid (tr2), capitate (c), and radius (r) are labeled. **B,** Fluid-sensitive coronal image emphasizing T2 relaxation demonstrates increased signal intensity (bright) within the inflammatory pannus, compatible with an increase in mobile water associated with inflammation. Increased signal intensity is evident within the lunate, scaphoid, and distal ulna, including focal areas within the distal row of carpal bones, corresponding to small erosions. Diffuse increased signal within the distal radius likely reflects reactive marrow edema (*asterisk*).

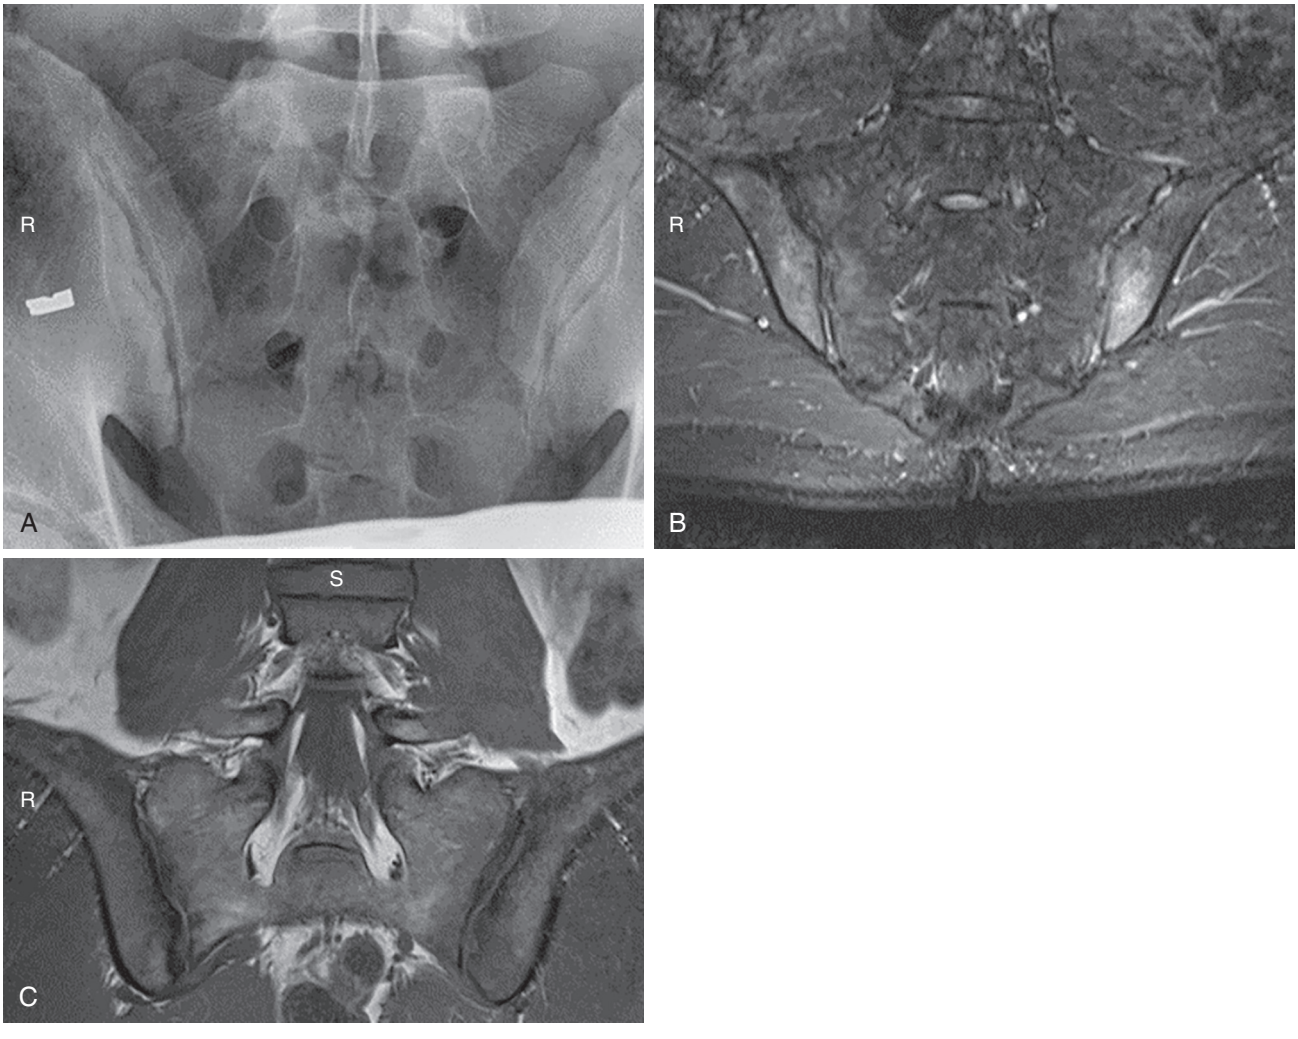

FIGURE 238-7. **Male age 42 years with low back pain and suspected seronegative arthritis. A,** Anteroposterior radiograph of the sacroiliac joints showing sclerosis involving the iliac portions of the joints bilaterally, with widening and probable erosion of the right sacroiliac joint. **B,** Oblique coronal fluid-sensitive, fat-suppressed T2-weighted. **C,** Oblique coronal T1-weighted images of the sacroiliac joints display symmetric combinations of low signal on T1 (dark areas), in part reflecting sclerosis, and high signal on T2 (bright areas), reflecting superimposed marrow edema. These features can be used to assess disease chronicity and activity.

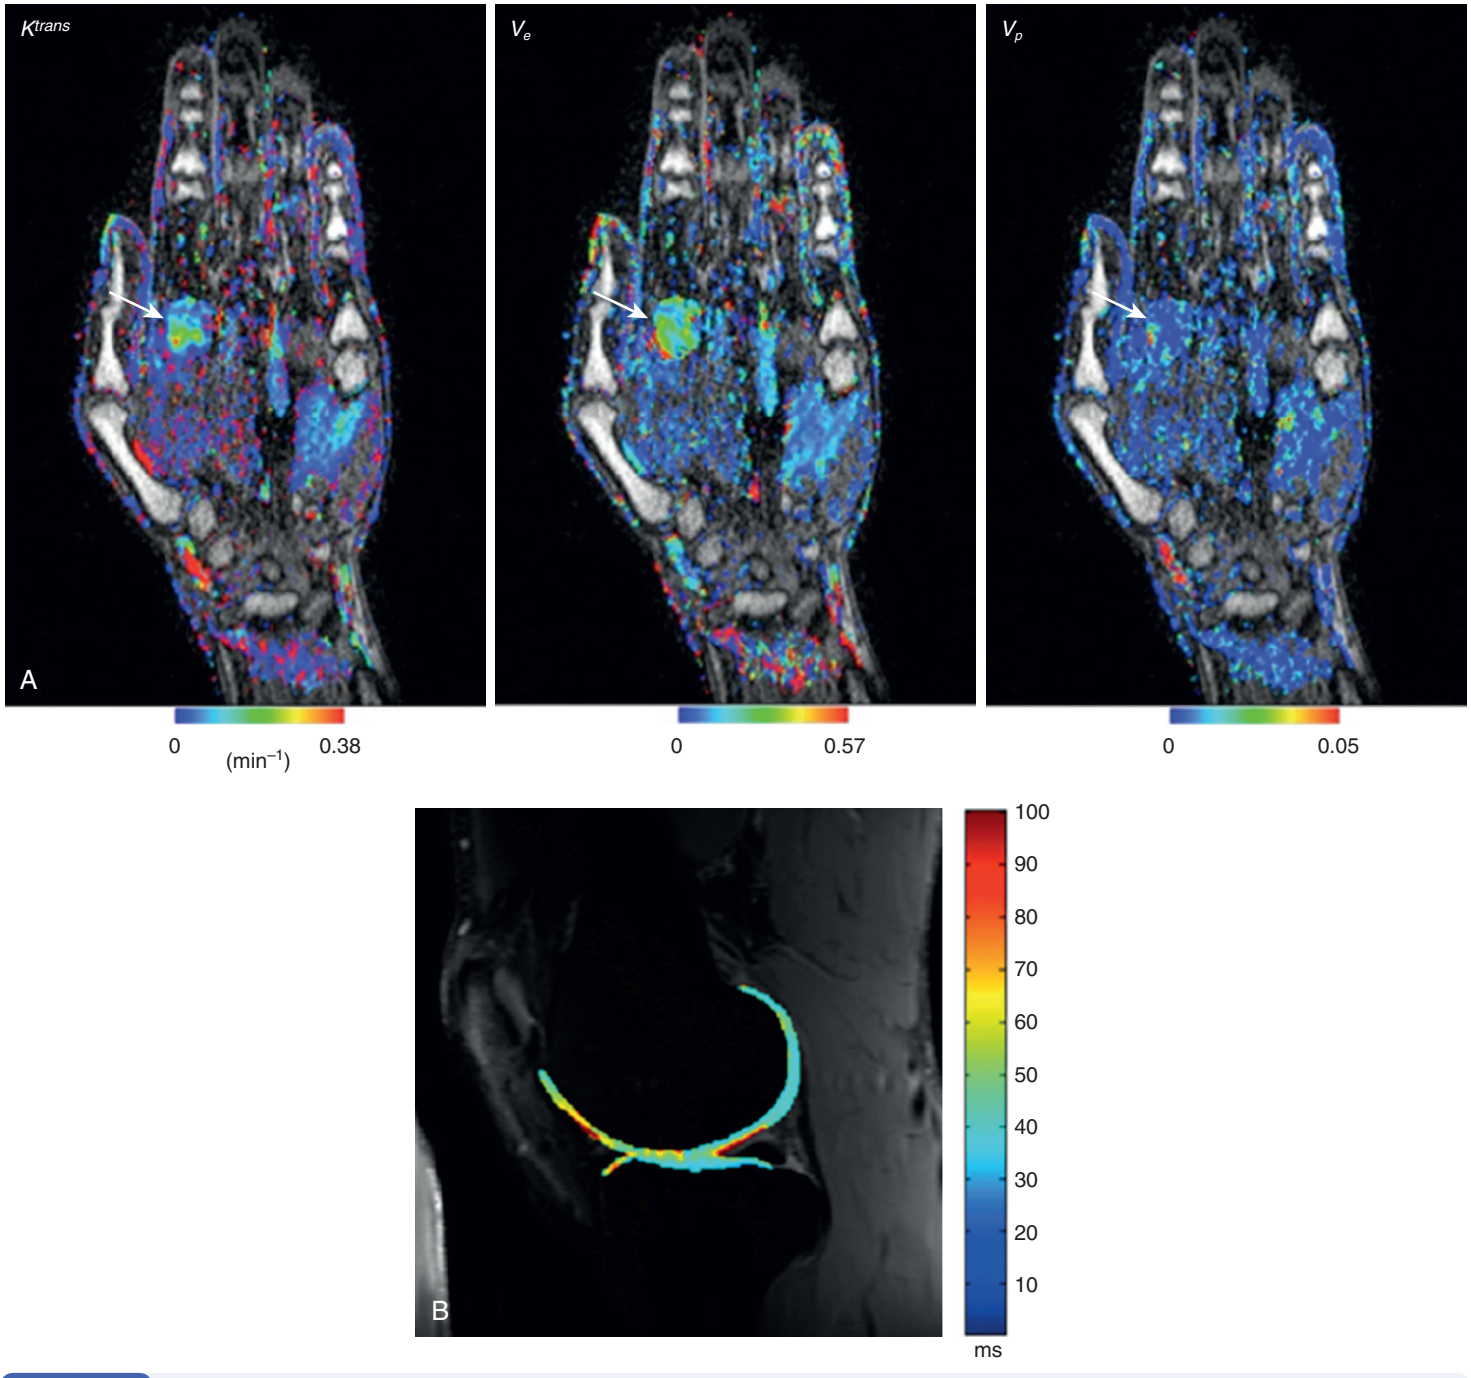

FIGURE 238-8. Functional magnetic resonance imaging. A, Parametric image derived from fitting a two-compartment model of soft tissue and synovial enhancement following intravenous administration of contrast material. Three parameters extracted from the time-intensity curves are displayed as parametric images: K^{trans} (*left*) provides a measure of contrast exchange into the extravascular soft tissues; V_e (*center*) and V_p (*right*) reflect the relative distribution volumes for the extravascular space and plasma, respectively. The *arrows* depict a region of increased synovial volume and enhancement at the second metacarpophalangeal joint. Increased values of K^{trans} and V_e illustrate increased vascular permeability at the site of inflammation. (Courtesy of Dr. Luis Beltran.) **B**, Sagittal T2 map of the knee in which relative T2 relaxation is color encoded, showing regions of higher cartilage T2 values at the femoral condyle and tibial plateau. This pattern reflects alterations in cartilage collagen architecture and water content and possibly early osteoarthritis. (Courtesy of Dr. Gregory Chang.)

Measurements and parametric images of apparent diffusion coefficient (ADC) provide a method to quantify soft tissue edema present in inflammatory states and may help to differentiate tissue inflammation from other potential sources of increased T2 contrast.[8] The loss of restrictive diffusion has likewise been employed as a quantitative metric and imaging tool to assess collagen breakdown in articular cartilage that occurs in early osteoarthritis.

The widely used contrast for MRI studies is a neutral hydrophilic salt of the gadolinium chelate, gadolinium diethylenetriamine-penta-acetic acid (Gd-DTPA). Gadolinium can be injected intravenously or directly into the joint. Intravenous injection (indirect magnetic resonance arthrography) carries the contrast in the vascular system to areas of hyperemia and inflammation (see Fig. 238-8). It can be used for assessment of synovial activity in inflammatory joint diseases. Gadolinium is taken up in inflamed synovium and is able to demonstrate thickened pannus. The slope of the early time–signal intensity curve provides a measure of tissue perfusion and can quantify inflammatory activity. Contrast material excreted into the synovial fluid provides excellent depiction of intra-articular structures and can be used in lieu of arthrographic direct techniques. In glycosaminoglycan-depleted cartilage, there can be delayed uptake of contrast into the cartilage, which would normally be inhibited by the negatively charged molecules.

Patients with renal disease who receive IV injection of gadolinium can develop nephrogenic systemic fibrosis (Chapter 246). When the kidney cannot sufficiently clear out the gadolinium, it produces fibrosis of many tissues, including the skin, muscle, heart, nerves, and pleura. The changes in the skin with nephrogenic systemic fibrosis are usually bilateral and

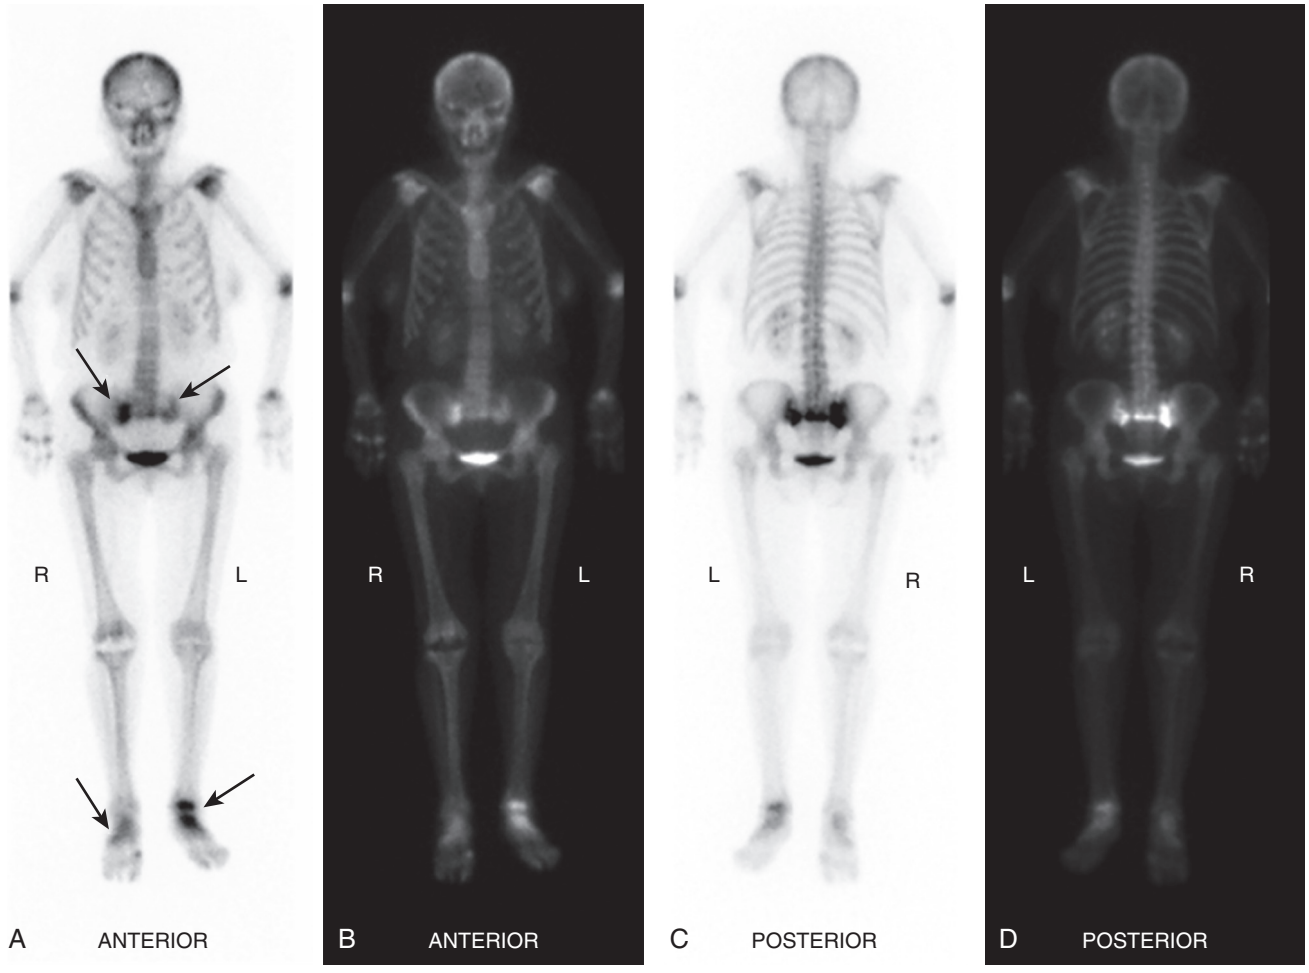

FIGURE 238-9. **Rectilinear bone scan in a patient with back pain. A, B,** Anterior and **(C, D)** posterior delayed images of the axial and appendicular skeleton demonstrate increased tracer uptake in the region of the sacral ala, left ankle, and right midfoot (*arrows*). Follow-up radiographs confirmed the presence of bilateral sacral ala fractures. Note that the central pooling of tracer in the expected location of the urinary bladder is normal. Bone scans provide a sensitive but nonspecific method to evaluate the appendicular and axial skeletons. Increased uptake in the feet in this patient was attributed to degenerative change. L = left; R = right.

symmetric, primarily involving the extremities and the trunk. These changes can mimic systemic sclerosis, but, unlike that disease, the face is usually spared. If renal function improves, the skin lesions may stabilize or improve, although the process progresses in some patients to affect mobility and cause severe pain.

Injection of dilute gadolinium into the joint (direct MR arthrography) is helpful for outlining structures and to detect morphologic damage. Injection is usually performed either under fluoroscopic or ultrasound guidance. This technique is particularly effective for the visualization of small structures such as the labrum of the hip or shoulder in the absence of a joint effusion. It is also helpful for demonstrating breakdown of soft tissue structures that normally prevent communication between joint compartments, such as the rotator cuff, triangular fibrocartilage of the wrist, and ligaments in the various joints. Techniques that enable image acquisition in near real time, as well as the development of MR-compatible needles now permit a variety of percutaneous procedures to be performed directly under MR guidance.

SCINTIGRAPHY

Scintigraphy can provide a global assessment of abnormal tracer uptake or can be performed using a targeted approach (Fig. 238-9). Images often provide high tissue contrast but are of relatively poor spatial resolution. Commonly used agents include tagged red blood cells to assess blood flow, agents that reflect bone metabolism (technetium-99m methylene diphosphate [Tc-MDP]), agents that reflect glucose metabolism (18-fluorine deoxyglucose [18-FDG]), and agents that concentrate at sites of inflammation, such as autologous white blood cells labeled with ^{111}In (indium) and ^{67}Ga-citrate (gallium). Clinical applications include detection of a variety of malignancies, osteomyelitis, vascular graft infection, multifocal infectious disease, inflammatory diseases (e.g., rheumatoid arthritis, vasculitis, inflammatory bowel disease, and sarcoidosis), fever of unknown origin, and infection of joint prostheses.

Bone scintigraphy uses Tc-MDP as the radioactive tracer. The isotope goes to areas of high bone turnover and vascular flow, as well as areas where calcium or bone is deposited. Three-phase bone scans, obtained at different intervals after injection, reflect the early vascular phase, the intermediate blood pool phase, and the late phase. Each phase allows for further characterization of the disease process. Abnormal tracer uptake is seen in areas of inflammation, infection, neoplasm, osteonecrosis, and fracture. The scan is most useful to identify the location of lesions within the skeleton but is nonspecific.

PET scans are often used in combination with either CT or MRI to achieve improved spatial registration, allow accurate estimates of soft tissue attenuation, provide high-quality anatomic images, and quantify metabolic activity.[9] Combined PET-CT or PET-MRI provides high-resolution images of abnormal metabolic activity and may ultimately provide the most definitive maps of inflammatory activity in patients with rheumatic disease.

239 INHERITED DISEASES OF CONNECTIVE TISSUE

REED E. PYERITZ

MUCOPOLYSACCHARIDOSES

DEFINITION

Proteoglycans are ubiquitous components of the extracellular matrix and the surfaces of cells, and they are among the largest and most complex of human molecules. Proteoglycans consist of a protein core to which are covalently bound glycosaminoglycans (GAGs; formerly called mucopolysaccharides) of several types: dermatan sulfate, heparan sulfate, keratan sulfate, and chondroitin sulfate. During normal degradation, these four polymeric molecules are cleaved from their protein core in lysosomes; then they, plus hyaluronan (a GAG lacking a protein core), are catabolized further in lysosomes in a stepwise fashion by more than a dozen enzymes. Genetic defects in any one of these enzymes lead to the accumulation of GAG metabolites in lysosomes, with profound disruption of cellular physiology. The phenotypes resulting from deficiencies of these catabolic enzymes are termed *mucopolysaccharidoses* and are classified into seven types (Table 239-1). Several additional storage disorders, termed *mucolipidoses*, are caused by a genetic defect in post-translational modification of lysosomal enzymes and share features with the mucopolysaccharidoses.

EPIDEMIOLOGY

All mucopolysaccharidosis disorders are rare, each with an incidence of one or fewer cases per 100,000 births, and are without ethnic predilection.

PATHOBIOLOGY

With the exception of mucopolysaccharidosis II (Hunter syndrome), which is X-linked, each of these disorders is autosomal recessive. All mucopolysaccharidoses are caused by deficiency of a single lysosomal enzyme responsible for a specific step in GAG metabolism (see Chapter 192). Catabolism of GAG proceeds normally until the step requiring the defective enzyme, when further normal metabolism halts. Although a minor degree of nonspecific breakdown occurs, resulting in urinary excretion of cleaved GAG that can be useful diagnostically, the accumulation of GAG within lysosomes of cells of mesenchymal origin, endothelium, and, in most cases, neurons causes widespread, progressive cellular dysfunction and clinical effects. Lysosomal enzymes are targeted to lysosomes by post-translational addition of mannose 6-phosphate. Deficiency of the phosphotransferase that catalyzes the first step in this reaction results in an inability to catabolize any GAG molecules. The catabolic enzymes, which normally would be transported into lysosomes, instead are secreted from the cell and are found in unusually high concentrations in plasma, providing one diagnostic test for mucolipidoses.

Pathology

All pathologic manifestations of mucopolysaccharidosis and mucolipidosis disorders worsen with age, and some are present from early developmental stages. Gross anatomic hallmarks are hepatosplenomegaly, marked skeletal alterations (termed *dysostosis multiplex*) that result in short stature and thoracic cage deformity, thickening and narrowing of airways and arteries, and coarsening of facial features. Although mental retardation is a prominent feature of some of these conditions, the brain may show only ventriculomegaly secondary to communicating hydrocephalus. On microscopy, mesenchymal cells show a cytoplasm full of apparently empty vacuoles; these are lysosomes from which GAG has been removed by fixation. Cells cultured from patients show greatly enlarged lysosomes filled with granular material. In the severe form of mucolipidosis, dense inclusions are present, which gave rise to the common name, *I-cell disease*.

CLINICAL MANIFESTATIONS

Each of the disorders in Table 239-1 shows a wide spectrum of clinical severity. This wide spectrum has led to a classification that gives the impression of separate disorders within some of the mucopolysaccharidosis and mucolipidosis types, but these represent the apparent ends of the continuum. Some

TABLE 239-1 MUCOPOLYSACCHARIDOSES AND MUCOLIPIDOSES

TYPE	EPONYM OR COMMON NAME	CLINICAL FEATURES	INHERITANCE	OMIM*	ENZYMATIC DEFECT
MPS IH	Hurler syndrome	DM and short stature; MR; corneal clouding; HS; heart disease; death in childhood	AR	252800	α-L-iduronidase
MPS IS	Scheie syndrome	Coarse facies; stiff joints; corneal clouding; aortic valve disease; normal intelligence and lifespan	AR	252800	α-L-iduronidase
MPS II	Hunter syndrome	Severe form: coarse facies, DM and short stature, HS; MR; no corneal clouding; death by late adolescence. Mild form: coarse facies, short stature; normal intelligence; survival to adulthood	XL	309900	Iduronate sulfatase
MPS IIIA	Sanfilippo A	Severe MR and hyperactivity; mild somatic changes	AR	252900	Heparan *N*-sulfatase
MPS IIIB	Sanfilippo B	Same as MPS IIIA	AR	252920	α-*N*-acetylglucosaminidase
MPS IIIC	Sanfilippo C	Same as MPS IIIA	AR	252930	Acetyl-coenzyme A: α-glucosaminide acetyltransferase
MPS IIID	Sanfilippo D	Same as MPS IIIA	AR	252940	*N*-acetylglucosamine 6-sulfatase
MPS IVA	Morquio A	Short stature and distinct skeletal dysplasia with odontoid hypoplasia and myelopathy; corneal clouding; normal intelligence; valvular heart disease	AR	253000	Galactose 6-sulfatase
MPS IVB	Morquio B	Same as MPS IVA	AR	253010	β-Galactosidase
MPS VI	Maroteaux-Lamy	DM and short stature; corneal clouding; normal intelligence; aortic stenosis; leukocyte inclusions; hydrocephalus in severe form	AR	253200	*N*-acetylgalactosamine
MPS VII	Sly syndrome	DM; HS; widely variable, including MR	AR	253220	β-Glucuronidase
MPS IX	—	Short stature; periarticular soft tissue masses	AR	601492	Hyaluronidase
ML II	I-cell disease	Similar to but more severe than MPS IH but with cellular inclusions; no mucopolysacchariduria	AR	252500	UDP-*N*-acetylglucosamine: lysosomal enzyme *N*-acetylglucosaminyl-1-phosphotransferase
ML III	Pseudo-Hurler polydystrophy	Short stature and mild DM; stiff joints; mild MR; survival to adulthood	AR	252500	Same as ML II arthropathy, coarse facies; variable but milder

*Entries in Online Mendelian Inheritance in Man, OMIM. McKusick-Nathans Institute of Genetic Medicine. Baltimore: Johns Hopkins University. http://omim.org.
AR = autosomal recessive; DM = dysostosis multiplex; HS = hepatosplenomegaly; MR = mental retardation; UDP = uridine diphosphate; XL = X-linked.

ABSTRACT

The inherited diseases of connective tissue are diverse in phenotypic characteristics, genetic and molecular causes, and effects on health. Among more than 200 conditions, some of the more common are the mucopolysaccharidoses, Marfan syndrome, the Ehlers-Danlos syndromes, the osteogenesis imperfecta syndromes, and pseudoxanthoma elasticum. In their severe forms, all can shorten life expectancy. Fortunately, therapies such as medication, enzyme replacement, and gene therapy are becoming more frequent and effective.

KEYWORDS

mucopolysaccharidoses
Marfan syndrome
Ehlers-Danlos syndromes
osteogenesis imperfecta

of the disorders without treatment result in death by adolescence (Hurler syndrome,[1] severe Hunter syndrome,[2] mucolipidosis II), but others are commonly compatible with survival to adulthood.

The milder end of the mucopolysaccharidosis I spectrum, Scheie syndrome, may not be diagnosed until adulthood; patients present with stiffened joints, corneal clouding and glaucoma, carpal tunnel syndrome, and aortic valvular disease. Stature and intelligence are not affected. The main health risks are cardiac valvular involvement, thickening of meninges that can produce a myelopathy, and thickening of the upper airways that can produce obstructive symptoms and sleep apnea.

Mucopolysaccharidosis II, Hunter syndrome, is distinctive because it is X-linked (affecting males almost exclusively), and the cornea shows little overt clouding. Cervical myelopathy, obstructive airway disease, and cor pulmonale are important concerns. A combined conductive and neurosensory hearing loss is common.

Neither mucopolysaccharidosis IV (Morquio syndrome)[3] nor mucopolysaccharidosis VI (Maroteaux-Lamy syndrome)[4] affects intelligence. Both syndromes often are associated with severe skeletal changes, which are distinct radiographically but produce similar problems of kyphoscoliosis, pectus carinatum, restrictive lung disease, severe short stature, and joint degeneration. Cervical myelopathy resulting from a thickened dura is common to both disorders and is accentuated by odontoid hypoplasia in mucopolysaccharidosis IV. Thickening of the aortic and mitral valves may produce severe dysfunction necessitating their replacement. General anesthesia is especially hazardous because of the narrow upper and middle airways and cervical instability.

Patients with mucolipidosis III[5] (pseudo-Hurler polydystrophy) resemble patients with mucopolysaccharidosis VI but often have mild to moderate mental retardation. Aortic regurgitation is common.

DIAGNOSIS

Differential Diagnosis

Because clinical diagnosis of these conditions is difficult in young children, before most of the clinical features have progressed, many countries have instituted newborn screening.[6] The diagnosis should be considered in any person with hepatosplenomegaly and coarsening of the facial features. Evaluation requires a pedigree analysis, ophthalmologic examination, skeletal radiographic survey, echocardiography, and analysis of the urine for excretion of GAGs. Often the specific mucopolysaccharidosis is evident from radiographs, the presence or absence of corneal clouding, and the pattern of mucopolysaccharidosis. Enzymatic analysis of leukocytes confirms the diagnosis. Patients with mucolipidoses do not show mucopolysaccharidosis but have marked elevation of all the GAG catabolic lysosomal enzymes in plasma.

TREATMENT

Ventriculoperitoneal shunting is necessary if intracranial pressure is elevated. Close attention to hearing and visual problems is essential throughout life. Many adults with mucopolysaccharidosis or mucolipidosis require surgery for carpal tunnel syndrome. Cardiovascular surgery for valvular or coronary disease may be necessary. All use of anesthesia is high risk because of the narrow airways and, in the case of mucopolysaccharidosis IV, atlantoaxial instability. For patients who remain ambulatory, selective joint replacement can be beneficial. Because of the morbidity associated with thoracic cage deformity, consideration should be given to stabilizing the spinal deformity before it becomes severe.

Replacement of the deficient enzyme by intravenous infusion is available or being evaluated for most of the mucopolysaccharidosis disorders. Laronidase (Aldurazyme) has been approved in the United States for treatment of mucopolysaccharidosis I. An infusion every 2 weeks for 1 year in adolescent and adult patients resulted in substantial reduction in hepatosplenomegaly and modest improvement in pulmonary function, sleep apnea, and joint mobility. Whether early institution of therapy in young children modulates mental retardation in the Hurler variant of mucopolysaccharidosis I is uncertain. Galsulfase (Naglazyme) has been approved for the treatment of mucopolysaccharidosis VI, in which somatic rather than neurologic problems predominate. Enzyme replacement should be started in all patients when diagnosed.[7]

Bone marrow transplantation has been attempted in many of the mucopolysaccharidosis disorders, with mixed success. The earlier transplantation occurs, the better the outcome in terms of somatic problems, but prevention of mental retardation has not occurred. Current recommendations based on consensus in Europe calls for hematopoietic stem cell transplantation for patients with Hurler syndrome before the age of 2.5 years.

MARFAN SYNDROME

DEFINITION

Marfan syndrome is an autosomal dominant, pleiotropic disorder caused by defects in the principal component of the extracellular microfibril, the large glycoprotein fibrillin-1.[8] The disease manifestations occur in multiple systems, especially the eye, skeleton, heart, aorta, lung, and integument. Notable features include dislocation of the ocular lens, tall stature with particularly long limbs and digits, deformity of the thoracic cage by pectus carinatum or excavatum with abnormal curvature of the spine, mitral and tricuspid valve prolapse, dilation of the sinuses of Valsalva and predisposition to aortic dissection, spontaneous pneumothorax, abnormal skin stretch marks, hernias, and dural ectasia. If untreated, patients often die before 30 or 40 years of age from aortic dissection or congestive heart failure.

EPIDEMIOLOGY

Marfan syndrome is a common mendelian disorder, with an estimated incidence of about 1 per 5000 births. Marfan syndrome is found throughout the world, without ethnic or geographic predilection.

PATHOBIOLOGY

Pathogenesis

Mutations in *FBN1*, which maps to human chromosome 15q21.1 and encodes fibrillin-1, cause Marfan syndrome and related connective tissue disorders. Several thousand distinct mutations have been found, and few occur in more than one family. Patients are heterozygous for mutations in *FBN1*, leading to autosomal dominant inheritance. Extracellular microfibrils are polymers of many fibrillin-1 molecules and are ubiquitous in the extracellular matrix of most tissues. Latent transforming growth factor-β (TGF-β) binding protein, which keeps the cytokine inactive, bears striking homology to regions of fibrillin. Abnormalities of either the quality or the quantity of microfibrils disrupt normal signaling by TGF-β, especially during embryonic development and postnatal growth. Studies in mice engineered to harbor human mutations in *FBN1* showed that excessive TGF-β signaling causes abnormal lung septation (the precursor to pneumothorax), bone overgrowth, mitral valve prolapse, muscular hypoplasia, and aortic dilation. This fundamental shift in understanding of the pathogenesis of Marfan syndrome has suggested novel therapies, such as with small molecules that affect the activity of TGF-β or its downstream signaling.

The features of Marfan syndrome are highly variable, even among relatives who share the same mutation in *FBN1*. This variability persists after accounting for the effects of age. Men tend to be affected more severely, for unclear reasons.

Pathology

The features of Marfan syndrome are age dependent. Some severely affected infants have flagrant features and often die of mitral regurgitation and heart failure despite aggressive management. At the other end of the clinical spectrum, Marfan syndrome merges with several related disorders and patients may not come to medical attention, let alone receive a definitive diagnosis, until adulthood.

None of the gross or microscopic pathologic changes is specific for Marfan syndrome. The medial degeneration of the aortic wall, characterized by disarray and fragmentation of the elastic fibers and increased proteoglycan (often inappropriately termed *cystic medial necrosis*), also can be seen in hereditary aortopathy syndromes and in older people with hypertension. Aortic dissection (Chapter 63) usually begins just superior to the aortic valve (type A) and often progresses to the bifurcation. Death usually results from retrograde dissection and hemopericardium. About 10% of dissections begin in the descending thoracic aorta (type B).

CLINICAL MANIFESTATIONS

The lens tends to be displaced superiorly, and usually the zonules remain intact. The retina is at increased risk for detachment, especially in patients who are highly myopic. Tubular bones overgrow, accounting for the disproportionate tall stature (dolichostenomelia), long digits (arachnodactyly), and sternal deformity. Ligaments may be lax, causing scoliosis and joint hypermobility. Alternatively, congenital contractures are common, especially of the elbows.[9] The palate typically is highly arched, and the dentition can be crowded and malocclused. Mitral valve prolapse occurs in about 80% of cases, and the valve leaflets become progressively thickened (myxomatous on histopathology). The mitral annulus may dilate and calcify. Aortic root dilation begins in the sinuses of Valsalva and progresses with age, albeit at highly variable rates (Chapters 55 and 63).[10] Most males with Marfan syndrome have an aortic root dimension above the upper limit of normal for their body surface area by adolescence. Some females show a slower progression and may have a root diameter near the upper limit of normal well into adulthood. The dilation usually does not

involve the distal ascending aorta. Spontaneous pneumothorax, resulting from rupture of apical blebs, occurs in about 5% of patients.[11] Stretch marks (striae atrophicae) occur over areas of flexural stress, such as the shoulders, breasts, and lower back. Some clinical features continue to progress as lifespan has been lengthened owing to successful cardiovascular surgery.[12] The neural canal in the lumbosacral region is enlarged in most people with Marfan syndrome; this may be visible on plain radiographs, especially if the neuroforamina are widened. Imaging by computed tomography or magnetic resonance imaging is diagnostic and should be used in patients with back pain and radicular symptoms. Dural ectasia progresses with age; large anterior meningoceles in the pelvis are a severe manifestation. In addition, sleep apnea and simple cysts in the liver and kidneys are common.

DIAGNOSIS

Differential Diagnosis

The conditions that overlap clinically and genetically with Marfan syndrome include familial aortic aneurysm, familial ectopia lentis, *m*itral valve prolapse, mild *a*ortic dilation, *s*triae, *s*keleton (MASS) phenotype (which includes many families with mitral valve prolapse syndrome), and Loeys-Dietz syndrome. Most of these conditions are diagnosed clinically, so differentiating among them is arbitrary. A careful family history is essential to this process. Molecular genetic testing is important. If the causative variant in *FBN1* is known in a family, analysis of DNA can be used effectively for presymptomatic or prenatal diagnosis. Loeys-Dietz syndrome, which is associated with generalized arterial tortuosity and susceptibility to dissection, is caused by pathogenic variants in either of two receptors for TGF-β, *TGFBR1* and *TGFBR2*, and molecular analysis is clinically available. Most mutations in *TGFBR1* and *TGFBR2* do not cause Loeys-Dietz syndrome but do predispose to familial thoracic aneurysm and dissection.

A question of Marfan syndrome arises most commonly in tall, lanky adolescents who have several minor skeletal features, nearsightedness, and athletic desires. A detailed ophthalmologic examination with full pupillary dilation and a transthoracic echocardiogram are essential components in the evaluation. If these test results are negative and no one in the family has a history of Marfan syndrome or aortic dissection, the patient probably can be reassured.

TREATMENT

All patients should be seen at least annually by a physician who manages the overall care. Most patients require annual ophthalmologic and cardiologic consultation and orthopedic consultation as required by specific problems. Lens subluxation often requires surgical correction.[13]

A number of studies, but only one randomized clinical trial, support the prophylactic use of β-adrenergic blockade from an early age to slow the rate of aortic root dilation and protect against aortic dissection. Although several trials found no benefit with the angiotensin receptor blocker losartan compared with atenolol,[A1] one large European trial showed a benefit of losartan on aortic root dilation rate[A2] and a reduction in the risk of aortic dissection and death, even when adjusted for the use of β-adrenergic blockers.[A3] Furthermore, irbesartan (150 mg increased to 300 mg daily as tolerated) can significantly reduce the rate of aortic dilation, especially in younger patients, with benefit also likely in patients who are also on a β-adrenergic blocker.[A4] Based on a meta-analysis of all trials, angiotensin receptor blockers appear to provide incremental benefit for reducing the progression of aortic dilation when added to β-adrenergic blockers.[A5,A6]

Prophylactic surgical repair of the aortic root has had the greatest beneficial impact. The composite graft, involving a prosthetic valve in a Dacron tube and implantation of the coronary ostia into the graft, was the first approach to produce markedly improved survival in these patients. More recently, replacement of the aneurysm and preservation of the native aortic valve should be considered first.[13] For adults, aortic root surgery should be strongly considered when the maximal aortic diameter reaches 45 mm, and a family history of aortic dissection should prompt earlier repair (Chapter 55).[14]

PROGNOSIS

Life expectancy for people with Marfan syndrome has improved markedly, to the point that many patients can expect survival to advanced years. Increased lifespan results in the appearance of new clinical problems, such as obstructive sleep apnea, peripheral arterial aneurysms, lumbosacral meningoceles, and truncal obesity. Some data suggest that aortic dissection and cardiovascular death are more likely in patients with *FBN1* haploinsufficiency with expression of the nonmutated allele than in patients with dominant-negative mutations in which abnormal fibrillin 1 coded by the mutated allele interacts with normal fibrillin 1 coded by the normal allele. Experimental data suggest that a fluoroquinolone antibiotic should be avoided in patients with Marfan syndrome because these may increase the risk of aortic dissection and rupture.[15]

EHLERS-DANLOS SYNDROMES

DEFINITION

The Ehlers-Danlos syndromes are clinically variable and genetically heterogeneous. Diagnoses are still based largely on the bedside examination. The unifying themes among these disorders are fragility of tissues, joint hypermobility, and skin hyperextensibility.

EPIDEMIOLOGY

No accurate data exist, but an incidence of about 1 in 5000 births is a reasonable estimate of how many individuals qualify for one of the Ehlers-Danlos syndrome diagnoses. Each type represents something of a clinical spectrum, with the mild end merging with what might be considered normal variation. The extent to which normal variation in joint hypermobility, skin elasticity, and tissue fragility represents genetic variation at loci that encode collagen or other extracellular matrix genes requires considerable research.

PATHOBIOLOGY

Pathogenesis

Defects in collagen and other proteins in the extracellular matrix of various tissues underlie all forms of Ehlers-Danlos syndrome that have been elucidated so far. The specific mutations occur in a variety of genes, with the effect of altering the structure, synthesis, post-translational modifications, or stability of the collagens involved. The known molecular defects are listed in Table 239-2.[16]

Pathology

Few findings in the routine pathologic evaluation distinguish among the various types of Ehlers-Danlos syndrome or even distinguish individual types from normal.[17] Thickness of the dermis is decreased in some forms, especially the vascular type, and the walls of arteries are reduced in thickness in this type. By electron microscopy, the classic, hypermobile, and kyphoscoliotic types have abnormal collagen fibers, especially when viewed in cross section (variable and often increased fiber diameter with an irregular outline). In the vascular type, some patients have dilated endoplasmic reticulum consistent with aberrant secretion of type III collagen molecules.

CLINICAL MANIFESTATIONS

The major and minor features of each Ehlers-Danlos syndrome are detailed in Table 239-2. Infants with classic Ehlers-Danlos syndrome often are born prematurely by 4 to 8 weeks because of rupture of fetal membranes. Diagnosis of the vascular and kyphoscoliotic types is important because of their cardiovascular features. The vascular type, previously termed *Ehlers-Danlos syndrome IV*, is characterized by spontaneous rupture of large arteries and hollow organs, especially the colon and uterus, and pneumothorax. Because these events carry considerable morbidity, life expectancy is reduced, on average, by more than half. During pregnancy, women with this form of Ehlers-Danlos syndrome are especially vulnerable to rupture of major arteries and the uterus. In the kyphoscoliotic type, aortic root dilation and aortic regurgitation can develop. Patients with most forms of Ehlers-Danlos syndrome are prone to develop mitral valve prolapse, and progression to mitral regurgitation (Chapter 60) occurs more often than in the common form of mitral valve prolapse.

DIAGNOSIS

Differential Diagnosis

By careful adherence to the clinical features shown in Table 239-2 and judicious use of laboratory tests, the various defined types of Ehlers-Danlos syndrome can be differentiated. Many other specific syndromes need to be excluded. The kyphoscoliotic type of Ehlers-Danlos syndrome in infants shares some features with severe Marfan syndrome. Patients with Larsen syndrome may resemble patients with the arthrochalasis type of Ehlers-Danlos syndrome. The skin redundancy and loss of elasticity of the dermatosparaxis type of Ehlers-Danlos syndrome is reminiscent of autosomal dominant cutis laxa, which is not associated with easy bruising or tissue fragility.

TABLE 239-2 EHLERS-DANLOS SYNDROMES

TYPE	FORMER NAME	CLINICAL FEATURES*	INHERITANCE	OMIM†	MOLECULAR DEFECT
Classic	EDS I and II	Joint hypermobility; skin hyperextensibility; atrophic scars; smooth, velvety skin; subcutaneous spheroids	AD	130000 130010	Structure of type V collagen caused by mutations in *COL5A1* or *COL5A2*
Hypermobility	EDS III	Joint hypermobility; some skin hyperextensibility, with or without a smooth, velvety texture	AD AR	130020 225320	? Tenascin-X (*TNX*)
Vascular	EDS IV	Thin skin; easy bruising; pinched nose; acrogeria; rupture of large- and medium-caliber arteries, uterus, and large bowel	AD	130050 (225350) (225360)	Deficient type III collagen (*COL3A1*)

*Listed in order of diagnostic importance.
†Entries in Online Mendelian Inheritance in Man, OMIM. McKusick-Nathans Institute of Genetic Medicine. Baltimore: Johns Hopkins University. http://omim.org.
AD = autosomal dominant; AR = autosomal recessive; EDS = Ehlers-Danlos syndrome; MVP = mitral valve prolapse; XL = X-linked.

The most difficult decision is whether any diagnosis of Ehlers-Danlos syndrome is warranted.[18] Patients who have only joint hypermobility without skin changes should not be labeled with Ehlers-Danlos syndrome; a diagnosis of familial joint hypermobility might be more appropriate. Familial joint instability involves a predisposition to dislocations of major joints that is rare in most types of Ehlers-Danlos syndrome except for arthrochalasis.

TREATMENT

Management of most skin and joint problems should be conservative and preventive. Sutures need to be placed with careful attention to approximating the margins and avoiding tension; removable sutures should be left in place for twice the usual time. Most instances of joint hypermobility and pain in Ehlers-Danlos syndrome do not require surgical treatment. Benefit often is derived from physical therapy designed to strengthen the muscles that provide support for the loose ligaments. All patients should receive genetic counseling about the mode of inheritance and their risk for having children affected with Ehlers-Danlos syndrome. The possibility of prenatal diagnosis exists for all of the Ehlers-Danlos syndrome types with defined molecular or biochemical defects.

The vascular type of Ehlers-Danlos syndrome requires particular surgical care; the ruptured arteries are difficult to repair because of the pronounced vascular fragility. Experienced vascular surgeons are having some success with prophylactic repair of vessels deemed to be at risk for dissection or rupture. One clinical trial suggested improved outcomes with prophylactic β-adrenergic blockade. Rupture of the bowel is a surgical emergency. Because the risk for uterine and vascular rupture is especially high during pregnancy in women with the vascular form, affected women should be advised that there is a substantial risk for death related to pregnancy and delivery. Patients should be advised to avoid contact sports and to treat blood pressure elevations aggressively. Arteriography and arterial lines should be avoided if possible. Biochemical and genetic screening holds the potential for reassuring relatives at risk that they do not have a defect in type III collagen.

The kyphoscoliotic type of Ehlers-Danlos syndrome may improve with large doses of vitamin C (1 to 4 g/day) because ascorbate is a cofactor for the enzyme that is deficient. No other metabolic or genetic therapy is effective in other forms of Ehlers-Danlos syndrome.

OSTEOGENESIS IMPERFECTA SYNDROMES

DEFINITION

The heterogeneous group of disorders called *osteogenesis imperfecta* includes, at one end of the severity spectrum, a type that is lethal prenatally or in the neonatal period and, at the other, such mild features that make distinguishing affected individuals from the general population is difficult. The unifying feature is hereditary osteopenia (insufficient bone), with primary defects in the protein matrix in bone and other tissues. The clinical syndromes all involve osteoporosis with liability to fracture (Chapter 225).

EPIDEMIOLOGY

No careful epidemiologic study has been performed, and the milder forms of type I osteogenesis imperfecta merge with the phenotypes of familial osteoporosis, fracture susceptibility, and joint hypermobility found in the general population. A crude estimate of the overall prevalence of osteogenesis imperfecta is 1 to 2 per 20,000 births. The neonatal lethal form (type II), which is almost always caused by a new mutation in a parental gamete, has an incidence of about 1 in 50,000 births.

PATHOBIOLOGY

Pathogenesis

Most patients in whom mutations have been found usually have defects in the two genes that encode the procollagen chains of type I collagen, *COL1A1* and *COL1A2*. Type I collagen is composed of two α1(I) and one α2(I) procollagen chains; the mature fiber requires considerable post-translational modification, which occurs appropriately only if the three procollagen chains have intertwined to form a triple helix that is perfect and completed at the right speed. A mutation that affects formation of the triple helix, such as substitution of one of the mandatory glycine residues that occurs at every third position, also has adverse effects on the modifications that render the molecule capable of forming effective mature fibers. As a result, a single nucleotide change resulting in a missense mutation can have profound effects on the extracellular matrix and produce a severe condition. Alternatively, and at first glance paradoxically, a mutation that eliminates an entire allele, or at least production of any product capable of intertwining with normal procollagen chains, has a much milder effect on the extracellular matrix and on the severity of osteogenesis imperfecta. Examples of the most common classes of mutations are shown in Table 239-3. Hundreds of pathogenic variants occur. Patients with mutations in *COL1A1* or *COL1A2* are heterozygous, and thus the most common forms of osteogenesis imperfecta are inherited as autosomal dominant traits. Several autosomal recessive forms of osteogenesis imperfecta occur because of mutations in genes that encode enzymes that process type I collagen into mature fibrils.

TABLE 239-3 OSTEOGENESIS IMPERFECTA

TYPE	CLINICAL FEATURES	INHERITANCE	OMIM*	BASIC DEFECTS
I	Fractures variable in number; little deformity; stature normal or nearly so; blue sclerae; hearing loss common but not always present; DI uncommon	AD	166200	Typically, one nonfunctional *COL1A1* allele
II	Lethal in utero or shortly after birth; many fractures at birth typically involving ribs (may appear "beaded") and other long bones; little calvaria; pulmonary hypertension	AD	166210	COL1A1 or *COL1A2:* substitution of glycyl residues; occasionally deletions of a portion of the triple-helical domain
		AR	259400	Deletion in *COL1A2* plus a nonfunctional allele
III	Fractures common, but long bones progressively deform starting in utero; stature markedly reduced; sclerae often blue but become lighter with age; DI and hearing loss common	AD	259420	One single amino acid substitution
		AR (rare)	259440	Two mutations in *COL1A1* and/or *COL1A2* (rarely)
IV	Fractures common; stature usually reduced; bone deformity common but rarely severe; scleral hue normal to grayish; hearing loss variable; DI common	AD	166220	Point mutations in *COL1A1* or *COL1A2*
			166240	Exon skipping mutations in *COL1A2*
V	Similar to type IV without DI or blue sclerae; fractures develop hyperplastic callus; calcification of the interosseous membrane between the radius and ulna	AD	610967	?
VI	Similar to type IV without DI, blue sclerae or wormian bones; excess osteoid present in bone	?	610968	?
VII	Similar to types II or III with fractures at birth, blue sclerae, no DI; presence of rhizomelic limb shortening and coxa vara	AR	610682	Mutations in *CRTAP*
VIII	Similar to types II or III with fractures at birth	AR	610915	Mutations in *LEPRE1*
IX	Similar to types II or III with fractures at birth	AR	259440	Mutations in *PPIB*

*Entries in Online Mendelian Inheritance in Man, OMIM. McKusick-Nathans Institute of Genetic Medicine. Baltimore: Johns Hopkins University. http://omim.org.
AD = autosomal dominant; AR = autosomal recessive; DI = dentinogenesis imperfecta.

Pathology

Other than the gross pathology associated with the clinical manifestations, the most characteristic pathology is a primary reduction in bone matrix with secondary undermineralization.

CLINICAL MANIFESTATIONS

The major phenotypic features of osteogenesis imperfecta are shown in Table 239-3. Among the most common forms, the most severe type is type II, followed in decreasing order by types III, IV, and I. In type II, infants either are stillborn or die soon after birth of pulmonary failure secondary to the small thorax, which usually is compromised further by myriad rib fractures. A few infants have survived for at least a few years but require enormous attention to their medical needs.

Type III osteogenesis imperfecta may be confused with type II at birth, but survival alone helps make the distinction. Bony deformity is pronounced and not necessarily caused by fractures. Mobility is impaired, and most patients require a wheelchair at an early age. Stature may be severely compromised. Because of progressive vertebral column deformity and rib fractures, restrictive lung disease is a common problem as patients age; many die of pulmonary complications. Basilar impression causing compression of the brain stem and the craniocervical junction can produce central sleep apnea, headache, and upper motor neuron signs.

Patients with type IV osteogenesis imperfecta generally have reduced stature, some bony deformity, and abnormal teeth that are opalescent and wear easily (dentinogenesis imperfecta). As in type I osteogenesis imperfecta, the tendency to fracture is highest in childhood and lessens with adolescence. A distinguishing characteristic of type IV osteogenesis imperfecta is a normal scleral hue.

Type I osteogenesis imperfecta is probably the most common form and is associated with a bluish or blue-gray scleral hue. People with type I osteogenesis imperfecta who also have dentinogenesis imperfecta tend to have more severe skeletal problems. The risk for fracture diminishes during adulthood but reemerges as a major concern for women after menopause. Hearing impairment in all forms of osteogenesis imperfecta is common and age related, being rare before adolescence. The deficits are of either a mixed or a predominantly conductive form.

The recessive forms of osteogenesis imperfecta (types VI to IX) range in severity from type IV to type II and may have distinctive radiologic or histopathologic findings.

DIAGNOSIS

Differential Diagnosis

The range of diagnostic possibilities in a person with multiple fractures largely depends on age. In infancy, the genetic conditions hypophosphatasia, severe osteochondrodysplasias (e.g., achondrogenesis and forms of spondyloepiphyseal dysplasia), and Menkes syndrome need to be excluded when a diagnosis of type II or type III osteogenesis imperfecta is considered. The radiographic features eventually become entirely diagnostic, but often the neonatologist has to arrive at a definitive answer in short order. Analysis of serum alkaline phosphatase and copper can be helpful. In childhood, the most common situation leading to consideration of a mild form of osteogenesis imperfecta is child abuse. In this situation, the pattern of fracture is usually distinct, and bone mineralization should be normal if the child is the object of nonaccidental or repeated accidental trauma. Abnormal scleral hue, dentinogenesis imperfecta, and wormian bones (microfractures along the cranial sutures) all support the diagnosis of osteogenesis imperfecta. The legal and child-protective systems often request exclusion of osteogenesis imperfecta by analysis of collagen production from cultured skin fibroblasts or analysis of DNA for a mutation.

TREATMENT

Management of the skeletal complications largely depends on orthopedic, physical, and occupational therapy approaches.[19] Risedronate (2.5 or 5 mg daily) increases bone mineral density and reduces both first and recurrent fractures in children with osteogenesis imperfecta.[A7] The long-term goals are for the patient to maintain function and independence as an individual. These goals can be advanced in some patients by judicious use of intramedullary rods in the long bones of the legs; if mobility and especially ambulation can be maintained, the demineralization associated with inactivity can be avoided.

Unaffected parents of a child with osteogenesis imperfecta and all affected individuals should have genetic counseling. For the parents of a child with type II osteogenesis imperfecta, the possibility of germinal mosaicism (which has been well documented in this condition) should not be overlooked. If one parent has a "new" mutation in one of the type I procollagen genes and multiple gonadal cells carry this mutation, the risk for recurrence in future children is not negligible. If the mutation in the affected child can be defined, the risk for recurrence can be quantified (through molecular analysis of sperm) if the mutation arose in the father.

In older children, the disorder idiopathic juvenile osteoporosis should be considered in any patient seen initially with repeated fractures. Many osteochondrodysplasias are associated with short stature, skeletal deformity, and a tendency to fracture. Pyknodysostosis and osteopetrosis are associated with sclerotic bones rather than osteoporotic ones. In adulthood, early-onset osteoporosis may be confused with osteogenesis imperfecta (Chapter 225). Mutations in type I collagen also cause familial osteoporosis, and the skeletal phenotypes merge; patients with true osteogenesis imperfecta may have scleral, hearing, or dental abnormalities and a positive family history.

Analysis of the specific enzymes defective in the recessive forms of osteogenesis imperfecta is useful for establishing the diagnosis and enabling reproductive counseling and prenatal diagnosis if desired.

PSEUDOXANTHOMA ELASTICUM

DEFINITION

Pseudoxanthoma elasticum is a heritable disorder of connective tissue with pleiotropic manifestations wherever elastic fibers are found but primarily in the skin, eye, and vasculature. Life expectancy is reduced, on average, because of a predisposition to myocardial infarction and gastrointestinal hemorrhage.

EPIDEMIOLOGY

The exact frequency of pseudoxanthoma elasticum is unknown, but it is probably underdiagnosed. Rough approximations suggest a prevalence of 1 in 25,000 to 100,000 births. Males and females are equally affected, although women are more likely to seek medical attention out of concern for the skin changes.

PATHOBIOLOGY

Pathogenesis

In most families, pseudoxanthoma elasticum occurs as an autosomal recessive trait, which means, given relatively small sibships, that many patients will have no affected relatives. Apparent autosomal dominant inheritance may reflect expression in occasional heterozygotes. The gene for pseudoxanthoma elasticum maps to human chromosome 16 and encodes one of the adenosine triphosphate (ATP)-binding cassette transporters (*ABCC6*). Because of the prominent histopathologic feature of calcification of elastic tissue, this gene may be important in calcium homeostasis. It is unclear, however, whether calcification is a primary or a secondary phenomenon in pseudoxanthoma elasticum.

Pathology

The hallmark of pseudoxanthoma elasticum, and an important diagnostic clue, is the histopathologic finding of hyperproliferated elastic fibers in the mid-dermis; these fibers become fragmented, clumped, and calcified. An arteriolar sclerosis develops in the media of muscular arteries and arterioles; the lumen may become progressively and concentrically narrowed. Alternatively, microaneurysms can form. Thickening of the endocardium, especially in the atria, develops in some patients. In the eye, the Bruch membrane becomes calcified and fragmented.

CLINICAL MANIFESTATIONS

Because of the pleiotropic nature of pseudoxanthoma elasticum, the diagnosis initially may be suspected by any of a variety of clinicians, especially dermatologists, ophthalmologists, cardiologists, and gastroenterologists. The condition gains its name from the dermatologic feature of yellowish papules that appear at areas of flexural stress, especially the neck, groin, and popliteal and cubital fossae; in periumbilical regions; and on the buccal mucosa. The appearance of affected skin has been likened to that of a "plucked chicken." Over time, affected areas coalesce and become thickened.[20]

Changes in the eye begin as a generalized, subtle, mottled pattern in the retina (peau d'orange) and progress to the characteristic angioid streaks. The latter changes are not specific for pseudoxanthoma elasticum and can be seen in diabetes mellitus, sickle cell disease, and a variety of other conditions. Streaks represent breaks in the Bruch membrane, an elastic lamina that lies between the retinal vasculature and the choroid. Spontaneous hemorrhages, especially those involving the macula, lead to progressive visual loss.

Involvement of arteries of various calibers produces problems because of occlusion and hemorrhage.[21] The lifetime risk for serious gastrointestinal hemorrhage from any site, but especially the stomach, is about 10%. Hypertension is relatively common, in part because of involvement of the renal vasculature. Progressive occlusion of peripheral arteries leads to absence of pulses; acral ischemia is rare because of the development of collaterals. The risk for stroke, myocardial infarction, abdominal angina, and intermittent claudication is increased independent of other risk factors. Impaired left ventricular function is common in adults.

DIAGNOSIS

Differential Diagnosis

Whole exome sequencing is an efficient and sensitive way to make the diagnosis. An acquired form of pseudoxanthoma elasticum has been reported and is also of unclear etiology. This form is difficult to differentiate from a sporadic case in a family because of heterozygosity in the parents, but it tends to affect only the skin. As suggested by the name, the cutaneous features of pseudoxanthoma elasticum need to be differentiated from those of true xanthoma, which results from a disorder of lipid metabolism (Chapter 190). The dermatologic manifestations need to be differentiated from those of Miescher elastoma, elastic tissue nevi (Buschke-Ollendorff syndrome), and solar elastosis.

TREATMENT

No cure for or means of preventing pseudoxanthoma elasticum is known.[22] In many instances, careful attention to the ocular features by a retinal specialist experienced in pseudoxanthoma elasticum can delay but not prevent loss of vision. The risk for gastrointestinal hemorrhage suggests that patients should avoid gastric irritants such as aspirin, nonsteroidal anti-inflammatory drugs, and excessive alcohol. Stool should be checked regularly for occult blood, and angiography may be necessary to detect the source of bleeding. All standard risk factors for atherosclerosis should be managed aggressively. Complaints of chest pain should prompt a rigorous investigation for coronary artery disease. Angioplasty has not been reported to be effective, and the coronary lesions tend to be diffuse. Coronary artery bypass graft surgery has been performed, but long-term results have not been reported. It may be theoretically advantageous to use vein grafts rather than the internal mammary artery for bypass. The excessive wrinkling and pseudoxanthoma in exposed areas can be ameliorated by plastic surgery.

240 THE SYSTEMIC AUTOINFLAMMATORY DISEASES

DANIEL L. KASTNER

DEFINITION

The systemic autoinflammatory diseases (Table 240-1) are a group of disorders that are characterized by seemingly unprovoked inflammation, without evidence of high-titer pathogenic autoantibodies or antigen-specific T cells, thereby distinguishing them from the more classic autoimmune diseases.[1] The first conditions recognized as autoinflammatory were the hereditary recurrent fevers, which are a group of mendelian disorders characterized by episodic or fluctuating degrees of fever and localized inflammation. The scope of autoinflammatory disease has broadened to include other heritable illnesses, including disorders in which purulent or granulomatous inflammation predominates, as well as inherited disorders of the complement system (Chapter 37).[2] In numerous autoinflammatory conditions, some of which manifest in childhood and others that occur later in life, a complex interaction of germline genetic susceptibilities, somatic mutations, and environmental factors contributes to the manifestation of the disease. Autoinflammatory illnesses include systemic-onset juvenile idiopathic arthritis (Still disease), Behçet disease, and even the crystalline arthritides. Many of the monogenic inherited autoinflammatory diseases are now considered inborn errors of innate immunity (Chapter 35), the phylogenetically more primitive part of the immune system that uses germline membrane and intracellular receptors expressed in granulocytes and macrophages to mount the body's first line of defense against pathogens.

Autoinflammatory syndromes can be grouped by key pathogenic cytokines and inflammatory pathways that are dysregulated and may be targets for effective therapies.[3] These molecular targets include interleukin-1 (IL-1), type I interferons, and the NF-κB inflammatory signaling pathway.

INTERLEUKIN-1–RELATED PERIODIC FEVER SYNDROMES

The IL-1–associated autoinflammatory diseases are linked by markedly increased expression of or cellular responsiveness to this cytokine, and resolution of symptoms with IL-1 blockade. Interleukin-1α and interleukin-1β (IL-1α and IL-1β) are structurally related cytokines released from cells in response to a number of inflammatory stimuli, such as lipopolysaccharide. These cytokines mediate inflammatory responses by binding to a common receptor that is present on the surface of a wide variety of cell types and that signals to activate inflammatory genes through the nuclear factor-kappa B (NF-κB) transcription factor complex. IL-1 is part of a larger family of cytokines (including IL-18, IL-33, and IL-36) that bind to related receptors and share the property of not having a characteristic signal peptide that normally targets cytokines to secretory vesicles. As a result, the IL-1 family cytokines may be secreted only by dead or dying cells, which function as molecular markers of cellular stress, and can trigger beneficial inflammatory responses to infection and injury. IL-1β and IL-18 are unique in that they are not biologically active until cleaved by the protease caspase-1, which also cleaves intracellular gasdermin D to induce an inflammatory form of cell death known as pyroptosis. Caspase-1 is itself activated in cytoplasmic protein complexes that contain various sensor proteins, such as NLRP3 and the adapter protein ASC. These complexes are referred to as inflammasomes because of their ability to trigger IL-1–mediated inflammation. IL-1–related autoinflammatory diseases (described later) are caused by mutations in genes encoding proteins that are directly or indirectly involved in the activation of IL-1 and the resulting inflammatory cascade.

FAMILIAL MEDITERRANEAN FEVER

DEFINITION

Familial Mediterranean fever (FMF) is a recessively inherited disease that typically manifests with 12- to 72-hour episodes of fever and localized serosal, synovial, or cutaneous inflammation. Between attacks, patients usually feel completely well, although biochemical evidence of inflammation may remain, and some patients eventually develop systemic amyloidosis (Chapter 174).

EPIDEMIOLOGY

Familial Mediterranean fever is most common in individuals of Jewish, Arab, Armenian, Turkish, and Italian ancestry. The frequency of asymptomatic carriers of a single *MEFV* mutation in these populations is as high as 1 in 10, likely because heterozygosity is associated with protection against *Yersinia pestis* infection (Chapter 288).[4] With genetic testing, familial Mediterranean fever is now frequently recognized in both Ashkenazi (eastern European) and non-Ashkenazi Jewish populations, as well as in Mediterranean populations previously thought not to be at risk. Mutation-positive individuals with typical symptoms have been documented worldwide.

PATHOBIOLOGY

MEFV, which is the gene mutated in familial Mediterranean fever, encodes a 781–amino acid protein denoted pyrin (or marenostrin) that is expressed in granulocytes, monocytes, and dendritic cells, as well as in peritoneal, synovial, and dermal fibroblasts. The N-terminal 92 amino acids of pyrin are the prototype for a motif, the PYRIN domain, that is involved in cognate interactions between proteins; this domain defines a family of more than 20 human proteins, including pyrin itself, that are involved in the regulation of cytokine production (particularly the IL-1 family), NF-κB activation, and cell death. Most of the pathogenic familial Mediterranean fever–associated mutations in pyrin reside in the C-terminal domain encoded by exon 10 of *MEFV*. An even larger number of variants of unknown significance have been described in individual patients with a spectrum of inflammatory phenotypes, and some patients with clinical presentations similar to that of familial Mediterranean fever have been found to have pyrin mutations on only one allele. The assembly of pyrin-containing inflammasomes is activated by bacterial toxins that inactivate the GTPase RhoA, including toxins derived from *Clostridia, Yersinia,* and *Vibrio* species. RhoA inactivates pyrin by inducing phosphorylation of pyrin on N-terminal serine residues, which leads to sequestration of pyrin by 14-3-3 proteins and inhibition of pyrin's ability to promote processing of the cytokine IL-1β. Familial Mediterranean fever–associated mutations in *MEFV* render pyrin resistant to RhoA-mediated inactivation, thereby providing a mechanism for the heightened secretion of IL-1β by cells harboring familial Mediterranean fever–associated pyrin mutations. These mutations also confer resistance to an important virulence factor produced by *Yersinia pestis* (the agent of plague in humans). Additional evidence for the importance of pyrin phosphorylation in the regulation of IL-1β production is that mutations in one of the phosphorylation sites of pyrin are associated with a severe early-onset syndrome of autoinflammation and neutrophilic dermatosis (PAAND).

As a consequence of its ability to depolymerize microtubules, colchicine activates RhoA, probably through the release of the RhoA guanine-nucleotide-exchange factor GEF-H1 from microtubules. Activated RhoA leads to increased phosphorylation of pyrin, thereby inactivating its pro-inflammatory function, even in cells harboring familial Mediterranean fever–associated pyrin mutations. Microtubule inhibitors also block pyrin inflammasome assembly in a phosphorylation-independent fashion.

CLINICAL MANIFESTATIONS

Familial Mediterranean fever usually manifests in childhood, sometimes even in infancy, although approximately 10% of patients experience their first attack as adults. Infrequently, symptoms first appear in persons older than age 40 years.

Episodes of familial Mediterranean fever are more properly termed recurrent rather than periodic, and some patients associate attacks with psychological stress or physical exertion. Women of childbearing age sometimes experience their attacks with menses, with remissions during pregnancy. Some patients are unaware of fever during the attacks, but fever is almost always observed when sought. Serosal involvement is usually peritoneal or pleural. Abdominal attacks are the most frequent, and they may vary from mild discomfort to frank peritonitis, with boardlike rigidity, direct and rebound tenderness, and air-fluid levels on upright films of the abdomen. Regardless of the severity of the abdominal attack, constipation is much more common than diarrhea. If a laparotomy or laparoscopy is performed during an attack, a small amount of sterile exudate rich in polymorphonuclear leukocytes may be found. Except for serosal inflammation, the appendix is normal. Repeated abdominal attacks

ABSTRACT

The systemic autoinflammatory diseases are a group of disorders characterized by seemingly unprovoked inflammation, without evidence of high-titer pathogenic autoantibodies or antigen-specific T cells, thereby distinguishing them from the more classic autoimmune diseases. The first conditions recognized as autoinflammatory were the hereditary recurrent fevers, which are a group of mendelian disorders characterized by episodic or fluctuating degrees of fever and localized inflammation. The scope of autoinflammatory disease has been broadened to include other heritable illnesses, including disorders in which purulent or granulomatous inflammation predominates, as well as inherited disorders of the complement system. Many of the inherited autoinflammatory diseases are now considered inborn errors of innate immunity, although acquired somatic mutations that affect the innate immune system are also increasingly recognized. These diseases can be subdivided based on the cytokine or inflammatory pathway that is primarily affected, such as disorders affecting interleukin-1, type I interferon, or the NF-κB signaling pathway. These categories are also helpful in guiding therapeutic approaches.

TABLE 240-1 SYSTEMIC AUTOINFLAMMATORY DISEASES: A PARTIAL LISTING

INHERITED AUTOINFLAMMATORY DISEASES	INHERITANCE	GENES OR RISK FACTORS	OMIM*
INTERLEUKIN-1-BETA–RELATED DISORDERS			
Familial Mediterranean fever (FMF)	Autosomal recessive	*MEFV*†	249100
Pyrin-associated autoinflammation with neutrophilic dermatosis	Autosomal dominant	*MEFV*†	608068
Tumor necrosis factor receptor–associated periodic syndrome (TRAPS)	Autosomal dominant	*TNFRSF1A*†	142680
Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS)/ Mevalonate kinase deficiency (MKD)	Autosomal recessive	*MVK*†	260920
Neonatal-onset multisystem inflammatory disease (NOMID)/Muckle-Wells syndrome (MWS)/familial cold autoinflammatory syndrome (FCAS)	Autosomal dominant/de novo	*NLRP3* (formerly *CIAS1*)†	607115 191900 120100
Schnitzler syndrome	Sporadic	*NLRP3* mosaic mutations (some)	
Multiple self-healing palmoplantar carcinoma	Autosomal dominant	*NLRP1*†	606636
Familial keratosis lichenoides chronica			615225
Autoinflammation with arthritis and dyskeratosis			617388
Deficiency of interleukin-1 receptor antagonist (DIRA)	Autosomal recessive	*IL1RN*†	147679
Deficiency of the IL-36R antagonist (DITRA)	Autosomal recessive	*IL36RN*†	605507
INTERFERON-RELATED AUTOINFLAMMATORY SYNDROMES (INTERFERONOPATHIES)			
Aicardi-Goutières syndrome	Autosomal recessive or autosomal dominant	*TREX1, RNASEH2A, 2B, 2C SAMHD1, ADAR (DRADA) IFIH1 (MDA5), LSM11, RNU7-1*	225750
STING-associated vasculopathy with onset in infancy (SAVI)	De novo	*TMEM173*†	612374 615934
COPA (coatamer subunit α) syndrome	Autosomal dominant	*COPA*†	601924
Proteasome-associated autoinflammatory diseases (PRAAS)/Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE)	Autosomal recessive, autosomal dominant, or digenic	*PSMA3,*† *PSMB4,*† *PSMB8,*† *PSMB9,*† *PSMB10,*† *POMP,*† *PSMG2*†	256040
NF-KAPPA-B–RELATED AUTOINFLAMMATORY SYNDROMES			
RELA haploinsufficiency	Autosomal dominant	*RELA*†	618287 164014
Haploinsufficiency of A20 (HA20) syndrome	Autosomal dominant	*TNFAIP3*†	191163 616744
OTULIN deficiency (otulipenia)	Autosomal recessive	*FAM105B (OTULIN)*†	615712 617099
NEMO deleted exon 5 autoinflammatory syndrome (NDAS)	X-linked (de novo)	*IKBKG*†	300248 301081
Immunodeficiency, autoinflammation, and amylopectinosis	Autosomal recessive	*HOIL1/RBCK1,*† *HOIP/RNF31*	610924 612487
Early-onset sarcoidosis/Blau syndrome	Sporadic, autosomal dominant	*NOD2/CARD15*†	186580, 605956
COMPLEMENT DISORDERS			
Hereditary angioedema	Autosomal dominant	*C1NH*	106100
Early-onset protein-losing enteropathy, and thrombosis, intestinal lymphangiectasia, and intestinal inflammation	Autosomal recessive	*CD55*	125240 226300
Hemolytic-uremic syndrome	Autosomal dominant, sporadic	*CFH* (complement factor H)	235400
Age-related macular degeneration	Complex inheritance	*CFH* (complement factor H)	603075
OTHER AUTOINFLAMMATORY SYNDROMES			
Deficiency of ADA2 (DADA2)	Autosomal recessive	*ADA2*†	607575 615688
Syndrome of periodic fever with aphthous stomatitis, pharyngitis, and cervical adenopathy (PFAPA)	Complex inheritance	*IL12A, IL10, STAT4, CCR1-CCR3, HLA-B*15:01 HLA-DQB1*06:03, HLA-DRB1*13:01, HLA-DQA-01:03*	—
Autoinflammatory disease associated with *NLRC4* mutations	Autosomal dominant	*NLRC4*†	606831 616050
Systemic-onset juvenile idiopathic arthritis (SOJIA)/adult-onset Still disease	Complex inheritance	*HLA-DRB1*11, LACC1, IL6, MIF* polymorphisms	604302
Behçet disease	Complex inheritance	*HLA-B*51*, polymorphisms in *IL10, IL23R, CCR1-CCR3, STAT4, KLRC4, ERAP1, MEFV, TLR4, IL1A-IL1B, IRF8, CEPB-PTPN1, ADO-EGR2, RIPK2, LACC1, FUT2, IL12A, NOD2*	109650
Syndrome of pyogenic arthritis with pyoderma gangrenosum and acne (PAPA)	Autosomal dominant	*PSTPIP1*†	604416
Chronic recurrent multifocal osteomyelitis (CRMO)	Sporadic, autosomal recessive	*LPIN2,*† when associated with congenital dyserythropoietic anemia (Majeed syndrome)	259680
Syndrome of periodic fever with immunodeficiency and thrombocytopenia (PFIT)	Autosomal recessive	*WDR1*†	150550 604734
Neonatal onset pancytopenia, autoinflammation, rash, and hemophagocytic lymphohistiocytosis (NOCARH syndrome)	*De novo*	*CDC42*†	
Cleavage resistant RIPK1 induced autoinflammatory syndrome (CRIA)	Autosomal dominant	*RIPK1*†	618852 603453
TBK1 deficiency	Autosomal recessive	*TBK1*	
Retinal dystrophy, optic nerve edema, splenomegaly, anhidrosis, migraine headache (ROSAH) syndrome	Autosomal dominant	*ALPK1*†	614979 607347

may cause peritoneal adhesions, but ascites is rare. Pleurisy, usually unilateral, may accompany abdominal pain, or it may occur independently. Physical findings, if present, may include diminished breath sounds and a pleural friction rub, whereas chest radiograms may show a small effusion or atelectasis. With multiple attacks, pleural thickening may develop. Symptomatic nonuremic pericardial involvement has been reported but is unusual.

In adults, the arthritis of familial Mediterranean fever typically manifests as monoarticular involvement of the knee, hip, or ankle, and attacks of arthritis may persist for up to 1 week at a time. In children, oligoarticular or polyarticular joint involvement may occur. Large joint effusions are sometimes present, and the synovial fluid may have as many as 100,000 leukocytes/μL. In approximately 5% of patients who are not treated with prophylactic colchicine, chronic arthritis (usually of the hip or knee) may develop, often necessitating joint replacement surgery. Regardless of colchicine treatment or a particular human leukocyte antigen (HLA-B27) status, some patients with familial Mediterranean fever develop sacroiliitis. Arthralgia without frank arthritis is common in familial Mediterranean fever. The *MEFV* M694V mutation is a risk factor for both ankylosing spondylitis (Chapter 244) and Behçet disease (Chapter 249).[5]

Cutaneous manifestations of familial Mediterranean fever tend to be less common than serosal or synovial involvement. The characteristic skin lesion is erysipeloid erythema, which is a painful, demarcated erythematous area most often seen on the lower leg, ankle, or dorsum of the foot. This rash may occur independently, or it may accompany an episode of arthritis. Histologically, a mixed perivascular cellular infiltrate is seen. Other acute manifestations of familial Mediterranean fever include unilateral scrotal inflammation (the tunica vaginalis is an embryologic remnant of the peritoneal membrane) and myalgia, either with fever or, especially in children, without fever and induced by vigorous exercise. Henoch-Schönlein purpura may occur in children with familial Mediterranean fever, and polyarteritis nodosa is less frequently seen (Chapter 249).

DIAGNOSIS

Based on a simple recessive model of inheritance, two mutations in *MEFV,* in *trans,* should be identified to establish the genetic diagnosis of familial Mediterranean fever. Nevertheless, the interpretation of genetic testing is complicated by complex alleles that consist of various combinations of mutations in *cis,* as well as by the observations that as many as one third of patients with clinically typical familial Mediterranean fever have only one demonstrable mutation in *MEFV,* and a few patients with typical disease have no identifiable *MEFV* mutations. These latter two findings suggest that, under some circumstances, one *MEFV* mutation may be sufficient for symptoms or that additional disease-causing genes exist.

For these reasons, clinical data remain an essential part of the diagnosis of familial Mediterranean fever, and genetic testing plays an adjunctive role in settings in which clinical experience is limited.[6] Clinical criteria emphasize the duration of the attack (12 to 72 hours); recurrence of symptoms (three or more episodes); documented fever (rectal temperature >38° C); painful manifestations in the abdomen, chest, joints, or skin; and the absence of other causative factors. The differential diagnosis includes the other hereditary recurrent fever syndromes (Table 240-2), as well as other conditions specific to the clinical setting. For patients with recurrent abdominal pain, considerations include gynecologic disorders, porphyria (Chapter 194; which can be distinguished by hypertension during attacks, dominant inheritance, and urine porphyrins), and hereditary angioedema (Chapter 232; which usually does not cause fever). The syndrome of periodic fever with aphthous stomatitis, pharyngitis, and cervical adenopathy is probably the most common cause of unexplained recurrent fever in children and is also included in the differential diagnosis. In patients who present primarily with recurrent monoarthritis, joint aspiration for cultures and crystals may aid in excluding bacterial and crystalline arthritis.

Still disease in children (systemic-onset juvenile idiopathic arthritis) and adults (adult-onset Still disease) is also considered in the differential diagnosis. Adult-onset Still disease[7] (see Table 240-1) is an uncommon autoinflammatory condition of unknown cause that is not considered to be hereditary. It is characterized by spiking fever, an evanescent salmon-pink maculopapular rash, arthritis, and neutrophilic leukocytosis. It can be clinically distinguished from familial Mediterranean fever by the pattern of fever (intermittent quotidian in Still disease as compared with discrete episodes in familial Mediterranean fever), the pattern of arthritis (chronic polyarthritis vs. intermittent monoarthritis), the characteristic skin involvement (evanescent rash vs. erysipeloid erythema), and the presence of lymphadenopathy (more common in Still disease).

TREATMENT

The mainstay of therapy is daily oral colchicine, which can prevent both acute attacks and the development of systemic amyloidosis.[A1] In adults, the therapeutic dose is 1.2 to 1.8 mg/day, and nearly 90% of patients note significant improvement at this dose. The major side effects are gastrointestinal, and they usually can be minimized by gradually increasing the dosage and avoiding milk products in patients who develop lactose intolerance. Most experts continue to prescribe colchicine to patients during pregnancy, with the recommendation that amniocentesis be performed to exclude trisomy 21, for which the risk may be slightly increased. Use of colchicine in lactating women is considered safe. Intravenous colchicine should be used with extreme caution, if at all, because fatal toxicity has been reported in patients who are already receiving oral colchicine.

In adult patients who are poorly responsive to colchicine or who cannot tolerate therapeutic doses, canakinumab, a recombinant human anti–human-IL-1β antibody (starting at 150 mg subcutaneously and increasing to 300 mg if needed), is usually safe and effective in preventing flares.[A2,A3]

PROGNOSIS

Effective control of flares with colchicine and/or IL-1 inhibition prevents the development of secondary amyloidosis and appears to result in a normal life expectancy. Before the widespread use of colchicine prophylaxis, however, systemic AA amyloidosis (Chapter 174) was a frequent complication of familial Mediterranean fever, because of the ectopic deposition of a misfolded fragment of serum amyloid A, which is an acute phase reactant, in the gastrointestinal tract, kidneys, spleen, lung, testes, and adrenals. Malabsorption and nephrotic proteinuria leading to renal failure are the most common manifestations of AA amyloidosis. Cardiomyopathy is less common, and neuropathy and arthropathy are rare. Risk factors for amyloidosis include late diagnosis of familial Mediterranean fever, noncompliance with colchicine, male sex, and specific genotypes of the *MEFV* and *SAA* genes. Amyloidosis is less common with familial Mediterranean fever in the United States than in the Middle East. The diagnosis of amyloidosis in familial Mediterranean fever is best made by rectal or renal biopsy. With early diagnosis, aggressive suppression of the acute phase response with colchicine or IL-1 inhibitors may lead to improvement. For patients with renal failure, however, early renal transplantation is preferred.

TABLE 240-2 CLINICAL CHARACTERISTICS OF SELECTED AUTOINFLAMMATORY DISEASES

CLINICAL FEATURE	FAMILIAL MEDITERRANEAN FEVER (FMF)	TUMOR NECROSIS FACTOR RECEPTOR–ASSOCIATED PERIODIC SYNDROME (TRAPS)	HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME (HIDS)	FAMILIAL COLD AUTOINFLAMMATORY SYNDROME/MUCKLE-WELLS SYNDROME/NEONATAL-ONSET MULTISYSTEM INFLAMMATORY DISEASE (FCAS/MWS/NOMID)	DEFICIENCY OF ADENOSINE DEAMINASE-2 (DADA2)
Typical ethnicity	Arab, Armenian, Italian, Jewish, Turkish	Any ethnicity	Dutch, other North European	European	Georgian Jewish origin for PAN-like disease
Age of onset	Childhood or adult	Childhood or adult	Early childhood, especially tied to immunizations	Childhood or adult (FCAS) Childhood (MWS) Infancy (NOMID)	Usually childhood
Attack duration	12-72 hr	Days to weeks	3-7 days	12-24 hr (FCAS) 1-2 days (MWS) Continuous, with flares (NOMID)	Occasional fevers Can have long asymptomatic periods
Abdominal involvement	Sterile peritonitis, constipation > diarrhea	Severe pain, vomiting, peritonitis	Sterile peritonitis, diarrhea, rarely constipation	Nausea (FCAS) Abdominal pain (MWS) Uncommon (NOMID)	Can be seen associated with abdominal vasculitis and infarctions, portal hypertension
Pleural attacks	Common	Common	Rare	Rare (MWS, NOMID)	Rare
Joint/bone involvement	Monoarthritis, rarely protracted arthritis in knee or hip	Arthritis in large joints, arthralgia	Arthralgia, symmetrical polyarthritis	Polyarthralgia (FCAS, MWS) Oligoarthritis (MWS) Clubbing (MWS, NOMID) Epiphyseal overgrowth, contractures, intermittent or chronic arthritis (NOMID)	Uncommon
Skin rash	Erysipeloid erythema on lower leg, ankle, foot	Migratory rash, underlying myalgia	Diffuse maculopapular rash, urticaria	Urticaria-like rash (cold-induced in FCAS)	Livedo reticularis, cutaneous vasculitis, scarring lesions, and necrosis can occur
Hematologic	Splenomegaly, occasional lymphadenopathy	Splenomegaly, occasional lymphadenopathy	Cervical adenopathy in children	Hepatosplenomegaly, adenopathy (NOMID, rare in MWS)	Cytopenias including pure red-cell aplasia, hypo-Ig, hepatosplenomegaly
Neurologic involvement	Aseptic meningitis?	Controversial	Headache	Headache (FCAS) Sensorineural deafness (MWS, NOMID) Chronic aseptic meningitis, intellectual disability (NOMID)	Recurrent ischemic strokes
Ophthalmologic involvement	Rare	Conjunctivitis, periorbital edema, rarely uveitis	Uncommon	Conjunctivitis (all) Uveitis (MWS, NOMID) Progressive vision loss (NOMID)	Retinal artery occlusion
Vasculitis	Henoch-Schönlein purpura (HSP), polyarteritis nodosa	HSP, lymphocytic vasculitis	Cutaneous vasculitis common, rarely HSP	Not seen (FCAS, MWS) Occasional in NOMID	Small and medium vessels, can present as polyarteritis nodosa
Systemic amyloidosis	Risk depends on *MEFV* and *SAA* genotypes; more common in Middle East	Occurs in ≈10%; risk increased with cysteine mutations	Uncommon, associated with V377I/I268T genotype	Rare (FCAS) 25% (MWS) May develop in adulthood (NOMID)	Can occasionally develop
Autoantibodies	Not usually seen	Not usually seen	Not usually seen	Not usually seen	ANCA usually negative
Effective treatments	Colchicine, IL-1 blockade	IL-1 blockade	IL-1 blockade	IL-1 blockade	TNF blockade, hematopoietic stem cell transplant for severe cytopenias

ANCA = antineutrophil cytoplasmic antibody; IL = interleukin; TNF = tumor necrosis factor.

HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME (MEVALONATE KINASE DEFICIENCY)

Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) was first described in six patients of Dutch ancestry who had extremely high levels of immunoglobulin D (IgD) in their serum. Hyperimmunoglobulinemia D, though quite rare, is now recognized in a broader ethnic distribution, although northern Europeans still predominate. The elevated IgD levels appear to be an epiphenomenon and do not correlate with the severity of disease, either among patients or in a given patient over time. Because modestly increased IgD levels can be seen in other inflammatory conditions and up to 20% of patients (particularly young children) with typical recurrent fevers and *MVK* mutations can have normal serum IgD levels, IgD levels alone are an unreliable diagnostic tool. Consequently, some experts prefer the term *mevalonate kinase deficiency* (MKD) to denote this illness.

This autosomal recessive disease is caused by mutations in *MVK,* which encodes the mevalonate kinase enzyme involved in the biosynthesis of cholesterol and nonsterol isoprenes.[8] Enzymatic activity in patients is markedly reduced but not absent. The isoprenoid deficiency resulting from *MVK* mutations is thought to be the basis for the clinical manifestations. Reduced

prenylation inactivates the GTPase RhoA, thereby abrogating its negative regulation of the pyrin inflammasome and resulting in increased production of IL-1β. IL-1β and increased body temperature can further decrease mevalonate kinase enzymatic activity, thereby creating a vicious circle in which infection or immunization can precipitate clinical attacks.

CLINICAL MANIFESTATIONS

One of the well-recognized clinical characteristics of hyperimmunoglobulinemia D is the provocation of attacks by immunizations. Other distinguishing clinical features include a very early age of onset (average age, 6 months), a 3- to 7-day duration of attacks (intermediate between familial Mediterranean fever and tumor necrosis factor [TNF] receptor-associated periodic syndrome), prominent cervical lymphadenopathy during attacks, polyarticular joint involvement, a diffuse maculopapular rash, the predominance of diarrhea over constipation with abdominal attacks, and the infrequency of pleuritic attacks or systemic amyloidosis.

The diagnosis can be established in a patient with recurrent episodes of fever and typical associated findings by documenting either two mutations in *MVK* or elevated levels of mevalonic acid, the substrate for mevalonate kinase, in the urine during attacks. Approximately 10% of patients with otherwise typical disease have only a single identifiable *MVK* mutation.

TREATMENT AND PROGNOSIS

Nonsteroidal anti-inflammatory drugs (NSAIDs; see Table 26-4) or glucocorticoids are sometimes useful in the treatment of the arthritic manifestations, but colchicine is generally not effective. Canakinumab (starting at 150 mg monthly subcutaneously in adults and increasing to 300 mg monthly if needed) is approved for the treatment of this disorder. Patients with hyperimmunoglobulinemia D have a normal lifespan, and attacks may become somewhat less frequent in adulthood.

TUMOR NECROSIS FACTOR RECEPTOR–ASSOCIATED PERIODIC SYNDROME

EPIDEMIOLOGY

Worldwide, the tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS) is the second most frequently diagnosed hereditary recurrent fever syndrome, behind familial Mediterranean fever. One of the first well-characterized families with what was later defined as TRAPS was of Irish ancestry, and the condition was termed familial Hibernian fever to emphasize the ethnic background and clinical differences from familial Mediterranean fever. However, with the discovery of TNF receptor mutations in families of other ancestries, the ethnically neutral TRAPS nomenclature is now used.

PATHOBIOLOGY

TRAPS is caused by mutations in *TNFRSF1A*, encoding the 55-kD receptor for TNF (TNFR1, p55, CD120a). The p55 TNF receptor comprises four cysteine-rich extracellular domains, a transmembrane region, and an intracellular death domain. To date, nearly all of the coding mutations described have been in the extracellular domains, and approximately one third are missense substitutions of cysteine residues that abolish highly conserved disulfide bonds. Studies indicate a complex pathogenetic picture, with the extracellular mutations causing diminished receptor shedding at the cell membrane, as well as defective trafficking and intracellular accumulation of mutant TNFR1 protein. Spontaneous signaling and possibly activation of the unfolded protein response leads to production of mitochondrial reactive oxygen species, constitutive activation of mitogen-activated protein kinases, and increased production of pro-inflammatory cytokines by myeloid cells harboring the mutant receptor.[9]

DIAGNOSIS

Although genetic testing is necessary for the diagnosis of TRAPS, clinical clues that can help distinguish TRAPS from familial Mediterranean fever include ethnicity (familial Mediterranean fever is seen predominantly in Mediterranean and Middle Eastern populations, whereas TRAPS has a more widespread distribution), mode of inheritance (autosomal recessive in familial Mediterranean fever, dominant in TRAPS), and duration of attacks, which tends to be longer in TRAPS and sometimes approaches continuous symptoms. The rash of familial Mediterranean fever is typically erysipeloid erythema on the lower extremity, whereas patients with TRAPS often have a distinctive erythematous rash, often with underlying myalgia, which may migrate on the trunk or centrifugally on the extremities. Ocular involvement, with periorbital edema, conjunctivitis, and occasionally even uveitis, is observed in TRAPS. Nevertheless, the abdominal, pleural, synovial, and even scrotal manifestations of the two diseases are rather similar. The usual age of onset for TRAPS is also in childhood.

Whereas a positive genetic test is not necessary to diagnose familial Mediterranean fever, the diagnosis of TRAPS requires the identification of a TNF receptor mutation. The diagnosis of TRAPS is established by the identification of *TNFRSF1A* mutations in the appropriate clinical setting. One variant, the substitution of glutamine for arginine at residue 92 (R92Q), is present in more than 1% of individuals with European ancestry and may be associated with a broader spectrum of symptoms than is typically seen in TRAPS, including early inflammatory arthritis or, in some cases, no symptoms at all. The substitution of leucine for proline at residue 46 (P46L) has been described in African American patients with TRAPS and is associated with a receptor shedding defect, but it is also seen among healthy West African controls. These findings establish a "gray zone" for the diagnosis of TRAPS and emphasize the potential role of polymorphisms in the recurrent fever genes in other more common inflammatory phenotypes.

TREATMENT

Treatment depends on the frequency and severity of attacks. Patients with relatively infrequent, mild episodes may respond to NSAIDs (Table 26-4). Patients with more severe attacks that occur infrequently may be treated with glucocorticoids under expert oversight, although increasing doses may be required as the episodes become more frequent and toxicities may become limiting. Canakinumab (starting at 150 mg subcutaneously monthly in adults and increasing to 300 mg monthly if needed)[10] is used in patients with frequent disease flares.

PROGNOSIS

Before the availability of IL-1 inhibition, the prolonged episodes of TRAPS were associated with substantial morbidity, and systemic AA amyloidosis was seen in approximately 10% of untreated patients. The extent to which current therapies will improve this prognosis awaits longer follow-up.

CRYOPYRIN-ASSOCIATED PERIODIC SYNDROMES: THE CRYOPYRINOPATHIES

Three rare, recurrent febrile disorders usually beginning early in life have been associated with mutations in *NLRP3* (formerly *CIAS1*), the gene that encodes a protein, usually denoted as cryopyrin or NLRP3, which is a key component of the NLRP3 inflammasome that activates caspase-1. These disorders are referred to as cryopyrinopathies or cryopyrin-associated periodic syndromes (CAPS). The least severe clinical phenotype is familial cold autoinflammatory syndrome (FCAS; formerly called familial cold urticaria), which is dominantly inherited and is notable for day-long attacks of chills, fever, headache, diffuse urticarial skin rash, arthralgia, and conjunctivitis, precipitated by generalized cold exposure. Amyloidosis is rare in FCAS. Of intermediate severity is Muckle-Wells syndrome (MWS), also dominantly inherited, in which 1- to 2-day episodes of chills, fever, urticarial rash, limb pain, and arthritis occur independently of cold exposure. Sensorineural hearing loss is a common feature of Muckle-Wells syndrome, and about 25% of patients develop AA amyloidosis, often in early adulthood. The most severe *NLRP3*-associated phenotype is neonatal-onset multisystem inflammatory disease (NOMID), known in Europe as chronic infantile neurologic cutaneous and articular (CINCA) syndrome. It is usually sporadic owing to the reduced reproductive fitness of most affected individuals. Fever and constitutional symptoms occur almost daily, often from birth, with generalized urticarial skin rash, a peculiar arthropathy characterized by epiphyseal overgrowth of the long bones, and central nervous system (CNS) involvement that includes chronic aseptic meningitis, uveitis, and cochlear inflammation, which may lead to intellectual disability, blindness, and deafness. In all three cryopyrinopathies, the rash is not true urticaria because

it has a neutrophilic rather than a mast cell infiltrate, and serum histamine levels are normal.

The protein mutated in all three disorders is NLRP3, a critical component of the eponymous NLRP3 inflammasome, which serves as an intracellular scaffold for the processing of IL-1β. The alternative name of this protein, cryopyrin, refers to its amino terminal PYRIN domain, the basis for a structural and functional relationship to the protein mutated in familial Mediterranean fever. Disease-associated cryopyrin mutations are thought to decrease the threshold for inflammasome activation, thereby increasing IL-1β production. The discovery that the NLRP3 inflammasome is also necessary for IL-1β production in response to crystalline forms of monosodium urate and calcium pyrophosphate connected the pathophysiology of these rare autoinflammatory diseases to crystal-induced arthritis (Chapter 252), which shares some clinical features, such as episodic, self-limited attacks, with autoinflammatory diseases.

DIAGNOSIS

Because there are patients with FCAS, MWS, and NOMID/CINCA without demonstrable germline *NLRP3* mutations, these diagnoses remain clinical, although genetic testing serves as a valuable adjunct and has greatly increased the recognition of all three conditions. Deep sequencing has identified somatic *NLRP3* mutations in many patients with symptoms consistent with CAPS who are negative for mutations by standard genetic testing. In addition, overlap syndromes that are intermediate between FCAS and MWS and NOMID/CINCA have been reported. NLRP3 is only one of a number of inflammasomes nucleated by other members of the NLR gene family, and gain-of-function mutations in *NLRP1*, encoding an NLR family member prominently expressed in the skin, underlie a spectrum of diseases characterized by keratotic skin lesions, arthritis, systemic inflammation, and self-healing palmoplantar carcinomas. Gain-of-function mutations in *NLRC4*, another intracellular NLR family member, have been reported in patients with a spectrum of symptoms ranging from FCAS-like disease to severe inflammatory disease with infantile-onset enterocolitis and macrophage activation syndrome. IL-18, a cytokine related to IL-1 which is also intracellularly processed by NLR and pyrin inflammasomes, is particularly elevated in patients with *NLRC4* mutations.

TREATMENT

In all three cryopyrinopathies, blockade with anakinra (a recombinant IL-1 receptor antagonist at 1 to 8 mg/kg subcutaneously per day in adults) is effective in controlling fever and acute phase reactants, and it also decreases CNS inflammation and end-organ damage in NOMID/CINCA. Rilonacept (another soluble IL-1 blocker given subcutaneously as a 320-mg loading dose followed by a 160-mg weekly dose in adults) and canakinumab (150 mg subcutaneously every 8 weeks in adults) can also be used in FCAS and Muckle-Wells syndrome, but they may be less effective than anakinra against NOMID/CINCA because of reduced penetration into the CNS.

PROGNOSIS

Although the febrile episodes of familial cold autoinflammatory syndrome interfere with daily life, especially in cold climates, life expectancy is normal. In untreated Muckle-Wells syndrome, deafness by early adulthood and AA amyloidosis are both common. Before anakinra treatment, the prognosis of NOMID was grim, with many patients either institutionalized or in renal failure owing to amyloidosis by early adulthood.

DEFICIENCIES OF IL-1 AND IL-36 RECEPTOR ANTAGONISTS

Deficiency of the IL-1 receptor antagonist (DIRA) is characterized by the neonatal onset of a pustular skin rash, multifocal osteomyelitis, periostitis, and, rarely, vasculitis. Fever is not a prominent finding, although acute phase reactants are markedly elevated. DIRA is caused by recessively inherited loss-of-function mutations in *IL1RN*, which encodes the IL-1 receptor antagonist (IL-1Ra). In DIRA, the lack of IL-1Ra leads to unopposed IL-1β and IL-1α signaling, whereas in the cryopyrinopathies, *NLRP3* mutations lead to inflammasome activation and increased IL-1β production.

Patients usually present within the first 2 weeks of life with skin lesions ranging from discrete crops of pustules to generalized severe pustulosis or ichthyosiform lesions. Histologic examination demonstrates extensive neutrophilic infiltrates in the dermis and epidermis. Typical radiographic findings include multifocal osteolytic lesions, periosteal elevation of the long bones, heterotopic ossification of the proximal femurs, and widening of the anterior rib ends. Bone biopsies demonstrate sterile purulent osteomyelitis, fibrosis, and sclerosis. DIRA patients respond dramatically to anakinra (1 to 8 mg/kg subcutaneously daily), which is a recombinant form of the protein they lack. In untreated patients, childhood mortality is high.

Loss-of-function mutations in *IL36RN*, which codes for a protein that serves a similar function as IL1RA in blocking the activity of the IL-1 family member IL-36, are associated with autosomal recessive inheritance of a syndrome termed *DITRA* (for deficiency of the IL-36 receptor antagonist), which is characterized by generalized pustular psoriasis, periodic fevers, and elevation of systemic inflammatory markers. IL-1 inhibition is generally not effective in the treatment of DITRA. Case reports suggest successful treatment of DITRA with inhibitors of IL-17 or IL12/23. Given the more limited tissue distribution of expression of the IL-36 receptor relative to the IL-1 receptor, the prognosis of DITRA may be better than DIRA, but the long-term outcome currently is not known.

THE INTERFERONOPATHIES: TYPE I INTERFERON–ASSOCIATED AUTOINFLAMMATORY DISEASES

A group of hereditary syndromes marked by systemic inflammation share induced gene expression of type I interferon target genes and cytokines and have been termed *interferonopathies*.[11] These diseases mimic some aspects of the antiviral state and congenital infection syndromes without a role for a known pathogen. Unlike most other autoinflammatory syndromes, autoantibodies can be found in some type I interferonopathies, thereby placing them on the spectrum between autoinflammatory and autoimmune disease.[12]

AICARDI-GOUTIÈRES SYNDROME AND ASSOCIATED DISEASES

A neonatal syndrome characterized by severe neurologic dysfunction and pleocytosis in the cerebrospinal fluid (CSF), Aicardi-Goutières syndrome (AGS) was first associated with mutations in the *TREX1* gene encoding a 3′–5′ DNA exonuclease. The definition of this syndrome has expanded to encompass mutations in a number of other genes associated with DNA or RNA modification or sensing; delayed onset past 1 year of age in some patients, particularly in patients with *IFIH1* or *ADAR* mutations; and extracerebral features such as glaucoma, hypothyroidism, and inflammatory bowel disease. Depending on the function of the encoded protein, both loss-of-function and gain-of-function mutations have been reported, but all lead to an increase in type I interferon signaling. Certain features, such as chilblains (Chapter 66), with cold-induced vascular-based inflammatory lesions in the hands and feet, overlap with those seen in pediatric lupus, and a small number of AGS patients meet clinical criteria for systemic lupus erythematosus. The diagnosis of AGS is established by genetic testing (see Table 240-1). Untreated, the various forms of AGS progress to severe neurologic dysfunction. Trials of Janus kinase (JAK) inhibitors are aimed at limiting the progression of the disease.

PROTEASOME-ASSOCIATED AUTOINFLAMMATORY SYNDROMES

The proteasome-associated autoinflammatory syndromes (PRAAS; also known as chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature, CANDLE) are a group of disorders caused by genetic mutations that lead to dysfunction of the proteasome, which is a macromolecular complex required for the normal degradation of proteins in both immune and nonimmune cells. To date, PRAAS/CANDLE mutations have been identified in the genes encoding the constitutive proteasome subunits (*PSMB4, PSMA3*), immunoproteasome components (*PSMB8, PSMB9, PSMB10*), and chaperone proteins (*POMP, PSMG2*).[13] Autosomal dominant, autosomal recessive, and digenic patterns of inheritance have been observed, depending on the specific gene(s) involved.

Proteasomal dysfunction leads to a type I interferonopathy that, depending on the specific genetic lesion(s), may cause recurrent fevers, neutrophilic panniculitis, lipodystrophy, metabolic syndrome, myositis, arthritis, joint contractures, developmental delay, cytopenias, and/or keratitis/episcleritis. Oral JAK inhibitors, particularly baricitinib, which block type I interferon signaling, have shown benefit for the treatment of PRAAS/CANDLE when given under expert supervision, but patients should be closely monitored for viral reactivation.[14]

STING-ASSOCIATED AUTOINFLAMMATORY SYNDROMES

The stimulator of interferon genes (STING) is an endoplasmic reticulum localized innate immune sensor of cytosolic double-stranded DNA, which may be present with double-stranded DNA viral infection. STING is activated by cyclic guanosine monophosphate-adenosine monophosphate (cGAMP), a second messenger that is synthesized by cyclic GMP-AMP synthase upon binding of double-stranded DNA. cGAMP normally induces STING to dimerize, thereby leading to the transcription of type I interferon–induced genes through the activation of interferon regulatory factor 3 (IRF-3) and TANK-binding kinase 1 (TBK1).

Gain-of-function mutations (most commonly de novo) in *TMEM173*, which encodes the STING protein, cause a severe neonatal-onset autoinflammatory disease denoted STING-associated vasculopathy with onset in infancy. These STING mutations cause STING to exit the endoplasmic reticulum, traffic to the Golgi, and become activated.

Owing to the expression of STING in endothelial cells, patients present with acral ischemia, which can cause a range of findings from Raynaud phenomenon to gangrene and loss of digits. Other manifestations include fever, interstitial lung disease with or without secondary pulmonary hypertension, polyarthritis, myositis, retinopathy, and developmental delay. Laboratory evaluation demonstrates increased acute phase reactants, cytopenias, and low titer autoantibodies. Patients experience significant morbidity and mortality owing to pulmonary involvement. Oral ruxolitinib, baricitinib, and tofacitinib under expert supervision have shown benefit, but patients should be closely monitored.

COPA syndrome is a relatively newly described disorder caused by heterozygous, dominantly inherited mutations in the coatomer subunit α, a component of a macromolecular complex that mediates retrograde Golgi-to–endoplasmic reticulum transport. Recent data indicate that COPA mutations cause cytoplasmic missorting of STING and ligand-independent STING activation.[15] The level of autoantibodies in COPA syndrome and the expansion of T_H17 cells indicate that this disorder is on the spectrum between autoinflammatory and autoimmune disorders. Patients with COPA syndrome bear phenotypic similarity to STING-associated vasculopathy with onset in infancy, including an early age of onset, capillaritis, interstitial lung disease, and increased type I interferon signaling. Arthritis and immune-mediated renal disease are also observed in COPA syndrome. Promising case reports suggest benefit with the use of JAK inhibitors in COPA syndrome, but longer term follow-up is required.

AUTOINFLAMMATORY DISEASES ASSOCIATED WITH ACTIVATION OF NF-κB

Loss-of-function mutations in NF-κB signaling are well-recognized causes of immunodeficiency disease, including disorders caused by mutations in *IKBKG* and *TNFRSF13B*. More recently, autoinflammatory disorders have been described in which NF-κB signaling is directly or indirectly activated. These disorders can be caused by mutations in NF-κB subunits, such as RelA; mutations in molecules that induce post-translational modifications of the NF-κB signaling complex, such as A20 and OTULIN (ubiquitylation) and NF-κB essential modulator (NEMO; phosphorylation); and molecules that activate innate immunity through the NF-κB pathway, such as NOD2/CARD15.

RELA HAPLOINSUFFICIENCY

RELA encodes the p65 NF-κB subunit. Heterozygous truncating mutations in *RELA* cause a dominantly inherited condition termed haploinsufficiency of RelA, in which impaired NF-κB signaling and accentuated TNF-dependent cell death causes autoinflammation. Patients present with recurrent fevers and abdominal pain, with ulcerations in the mouth and throughout the gastrointestinal tract. Flares are accompanied by leukocytosis and elevated acute phase reactants, but autoantibodies are generally not present. Patients generally respond well to TNF inhibitors under expert supervision.

HAPLOINSUFFICIENCY OF A20 AND DISORDERS OF NF-κB REGULATION

TNFAIP3 encodes a protein, sometimes denoted A20, that plays a dual role in regulating NF-κB ubiquitylation. A20 removes K63-linked ubiquitin chains that ordinarily stabilize TNF-induced proinflammatory signaling complexes and adds K48-linked ubiquitin chains to the dissociated proteins, thereby targeting them for destruction by the proteasome. Dominantly inherited, heterozygous loss-of-function mutations in A20 lead to the persistence of proinflammatory signaling complexes and a syndrome termed haploinsufficiency of A20, which presents with early-onset systemic inflammation, arthralgia/arthritis, oral, genital, and/or gastrointestinal ulcerations, ocular inflammation, venous thrombosis, and, in some patients, autoantibodies and glomerulonephritis.

OTULIN (FAM105B) encodes a deubiquitylase that removes linear (Met1-linked) ubiquitin chains that may also stabilize TNF-induced proinflammatory NF-κB signaling. Biallelic loss-of-function mutations in *OTULIN* cause neonatal-onset fever, neutrophilic dermatitis/panniculitis, lipodystrophy, arthritis, vasculitis, diarrhea, and failure to thrive.

IKBKG encodes NEMO, a component of the IκB kinase complex that phosphorylates IκBα to activate NF-κB signaling. *De novo* X-linked *IKBKG* mutations that lead to the in-frame deletion of the domain encoded by exon 5 cause a syndrome characterized by increased activation of NF-κB and neonatal-onset fevers, sterile panniculitis, optic neuritis, chorioretinitis, organomegaly, and hemorrhagic stroke, denoted the *N*EMO *d*eleted exon 5 *a*utoinflammatory *s*yndrome (NDAS).[16]

Case reports suggest successful use of IL-1, TNF, and JAK inhibitors in the treatment of patients with HA20. Both IL-1 and TNF inhibitors have shown benefit in individual patients with biallelic mutations of *OTULIN*. Glucocorticoids have been used under expert supervision to control the autoinflammatory manifestations of NDAS.

GRANULOMATOUS ARTHRITIS, DERMATITIS, AND UVEITIS (BLAU SYNDROME)

NOD2/CARD15 encodes an intracellular sensor of bacterial muramyl dipeptides. Relatively low-penetrance, common variants of this gene affect the leucine-rich repeat domain of the encoded protein and are associated with Crohn disease (Chapter 127), whereas rare heterozygous high-penetrance mutations in the nucleotide-binding domain cause Blau syndrome and some cases of early-onset sarcoidosis (Chapter 83).

In Blau syndrome, the *NOD2* mutations are associated with increased NF-κB signaling.[17] Blau syndrome is a dominantly inherited illness presenting with early-onset granulomatous synovitis often complicated by cyst formation and camptodactyly (flexion contractures of the fingers and toes); granulomatous anterior and posterior uveitis, sometimes causing retinal detachment, glaucoma, cataracts, and blindness; and an intermittent papular rash with noncaseating granulomas. Lung or other visceral involvement is generally not present. However, visceral involvement of the liver and spleen is observed in early-onset sarcoidosis, which is phenotypically quite similar to Blau syndrome. Treatment with TNF inhibitors under expert supervision has markedly improved the prognosis of Blau syndrome.

OTHER INHERITED SYSTEMIC AUTOINFLAMMATORY DISEASES

SYNDROME OF PYOGENIC ARTHRITIS WITH PYODERMA GANGRENOSUM AND ACNE

The syndrome of pyogenic arthritis with pyoderma gangrenosum and acne (PAPA) is a rare, dominantly inherited autoinflammatory disease characterized by intermittent episodes of sterile pyogenic arthritis, pyoderma gangrenosum, and severe cystic acne. It is caused by mutations in the gene encoding proline-serine-threonine phosphatase–interacting protein 1 (PSTPIP1), also known as

CD2BP1. PSTPIP1 is a cytoskeletal protein that interacts with certain other proteins involved in the immune response, including CD2; the Wiskott-Aldrich syndrome protein (WASP); a phosphatase denoted PTP-PEST; and pyrin, the familial Mediterranean fever (FMF) protein. PAPA mutations abrogate the binding of PSTPIP1 to PTP-PEST, leading to hyperphosphorylation of PSTPIP1 and increased binding to pyrin. This finding is associated with markedly increased production of IL-1β and extremely high levels of total and free IL-18 in the blood.[18]

Early in life, PAPA tends to present with monoarticular or pauciarticular pyogenic arthritis, sometimes induced by trauma. As patients reach puberty, skin manifestations begin to predominate, including disfiguring cystic acne. Pathergy also may develop, and extensive pyoderma gangrenosum may require opiates for pain control. The diagnosis of PAPA syndrome is made by documenting *PSTPIP1* mutations in the appropriate clinical setting.

High doses of glucocorticoids have been used under expert supervision with varying success in PAPA, and patients with arthritis sometimes require aspiration, intra-articular glucocorticoids, or open drainage. Small case series support the use of anakinra or canakinumab for the arthritis and monoclonal anti-TNF antibodies for the pyoderma gangrenosum of PAPA. In the absence of treatment, arthritis may progress to severe joint damage and ankylosis.

ADENOSINE DEAMINASE-2 DEFICIENCY

A syndrome characterized by fevers, early-onset strokes, and vasculopathy or frank vasculitis mimicking polyarteritis nodosa has been found to be caused by autosomal recessive mutations in *ADA2* (formerly *CECR1*), which encodes adenosine deaminase-2 (ADA2). Although ADA2 shares enzymatic activity with intracellular adenosine deaminase that is encoded by the *ADA* gene, ADA2 is not necessary for the development of lymphocytes, and patients with deficiency of adenosine deaminase-2 (DADA2) do not initially present with severe combined immunodeficiency (SCID), as is the case for ADA deficiency. ADA2 is a secreted extracellular protein, and functional studies have found that ADA2 plays a role in vascular development and regulation of macrophage differentiation. Although this disease is generally diagnosed in childhood, it should be considered in the differential diagnosis of young adults with unexplained lacunar strokes, vasculitic skin lesions, and/or polyarteritis nodosa. Transfusion-dependent anemia and severe neutropenia are uncommon manifestations.

TNF inhibition under expert supervision is highly effective in preventing stroke.[19] Hematopoietic stem cell transplantation may be curative, both for cytopenias and vascular manifestations.

GENOME SEQUENCING AND THE DISCOVERY OF NEW AUTOINFLAMMATORY SYNDROMES AND INNATE IMMUNE PATHWAYS

A major attraction of the concept of the autoinflammatory diseases has been the molecular explication of numerous inborn errors of inflammation, an enterprise that has converged with the delineation of the innate immune system (Chapter 35). With advances in genome sequencing, the number of defined autoinflammatory diseases that are associated with dramatically elevated levels of total and free IL-18 in the blood has increased rapidly. Recently defined conditions include autoinflammatory periodic fever, immunodeficiency, and thrombocytopenia (PFIT), which is caused by mutations in the actin-regulatory gene *WDR1;* neonatal-onset pancytopenia, autoinflammation, rash, and hemophagocytic lymphohistiocytosis (NOCARH syndrome),[20] which is caused by mutations in *CDC42* that activate the pyrin inflammasome; and mutations in *MEFV,* which encodes pyrin. Taken together, these findings point to a poorly understood aspect of inflammasome activation that may be amenable to therapies targeting IL-18.

Other recent genomic discoveries implicate the cell death pathways of apoptosis and necroptosis in two different autoinflammatory disorders caused by mutations in *RIPK1* and *TBK1*.[21] Gain-of-function mutations in *ALPK1,* encoding a novel innate immune sensor for seven carbon sugars (which are made by gram-negative bacteria but not by mammals), cause an autoinflammatory syndrome characterized by retinal dystrophy, optic nerve edema, splenomegaly, anhidrosis, and migraine headache (ROSAH).[22] Genomic sequencing of children carrying the diagnosis of systemic-onset juvenile idiopathic arthritis has identified *LACC1* as an important regulator of immunometabolic function in macrophages, and genomic sequencing of patients with a form of chronic recurrent multifocal osteomyelitis has identified *LPIN2* as an important regulator of osteoclast differentiation in M2 macrophages.[23] Gain-of-function mutations in *PLCG2,* which encodes the phospholipase Cγ2 enzyme that has essential functions in B-cell receptor and Fc receptor signaling, cause a dominantly inherited autoinflammatory syndrome characterized by blistering skin lesions, bronchiolitis, arthralgia, ocular inflammation, and enterocolitis in the absence of autoantibodies.

SOMATIC MUTATION AND LATE-ONSET AUTOINFLAMMATORY DISEASE

An autoinflammatory disorder caused by myeloid-restricted somatic mutations in *UBA1*, which is one of the critical regulators of ubiquitylation in all cells,[24] is manifested by fever, relapsing polychondritis (usually affecting the nasal and/or auricular cartilage but sparing the trachea), neutrophilic dermatosis, medium-vessel vasculitis, pulmonary infiltrates, neutrophilic alveolitis, venous thromboembolism, macrocytic anemia, vacuoles in myeloid precursor cells in the marrow, and hypercytokinemia. Based on the demonstration of somatic *UBA1* mutations, this condition is termed VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) syndrome. Because *UBA1* is encoded on the X-chromosome, VEXAS syndrome is observed almost exclusively in men, usually over age 40 years. Given the high mortality rate, early allogeneic stem cell transplantation may be advisable.

Adult-onset syndromes resembling the inherited versions of both the cryopyrinopathies and TRAPS are caused by somatic mutations in *NLRP3* and *TNFRSF1A,* respectively. The discovery of these syndromes raises the possibility of somatic mutations in other adult-onset rheumatic diseases and emphasizes the likelihood of other genetic diagnoses that cut across the boundaries of current clinical syndromes.

241 OSTEOARTHRITIS

DAVID J. HUNTER

DEFINITION

Osteoarthritis is characterized by failed repair of synovial joint tissues after intra-articular stress. The resulting breakdown of cartilage and bone can lead to symptoms of pain, stiffness, and functional disability. However, synovial joint pathology and structural changes on imaging studies may correlate poorly with patient-reported symptoms.

EPIDEMIOLOGY

Osteoarthritis is a highly prevalent, disabling disease that affects more than 500 million people worldwide, with women disproportionately affected.[1] The

CD2BP1. PSTPIP1 is a cytoskeletal protein that interacts with certain other proteins involved in the immune response, including CD2; the Wiskott-Aldrich syndrome protein (WASP); a phosphatase denoted PTP-PEST; and pyrin, the familial Mediterranean fever (FMF) protein. PAPA mutations abrogate the binding of PSTPIP1 to PTP-PEST, leading to hyperphosphorylation of PSTPIP1 and increased binding to pyrin. This finding is associated with markedly increased production of IL-1β and extremely high levels of total and free IL-18 in the blood.[18]

Early in life, PAPA tends to present with monoarticular or pauciarticular pyogenic arthritis, sometimes induced by trauma. As patients reach puberty, skin manifestations begin to predominate, including disfiguring cystic acne. Pathergy also may develop, and extensive pyoderma gangrenosum may require opiates for pain control. The diagnosis of PAPA syndrome is made by documenting *PSTPIP1* mutations in the appropriate clinical setting.

High doses of glucocorticoids have been used under expert supervision with varying success in PAPA, and patients with arthritis sometimes require aspiration, intra-articular glucocorticoids, or open drainage. Small case series support the use of anakinra or canakinumab for the arthritis and monoclonal anti-TNF antibodies for the pyoderma gangrenosum of PAPA. In the absence of treatment, arthritis may progress to severe joint damage and ankylosis.

ADENOSINE DEAMINASE-2 DEFICIENCY

A syndrome characterized by fevers, early-onset strokes, and vasculopathy or frank vasculitis mimicking polyarteritis nodosa has been found to be caused by autosomal recessive mutations in *ADA2* (formerly *CECR1*), which encodes adenosine deaminase-2 (ADA2). Although ADA2 shares enzymatic activity with intracellular adenosine deaminase that is encoded by the *ADA* gene, ADA2 is not necessary for the development of lymphocytes, and patients with deficiency of adenosine deaminase-2 (DADA2) do not initially present with severe combined immunodeficiency (SCID), as is the case for ADA deficiency. ADA2 is a secreted extracellular protein, and functional studies have found that ADA2 plays a role in vascular development and regulation of macrophage differentiation. Although this disease is generally diagnosed in childhood, it should be considered in the differential diagnosis of young adults with unexplained lacunar strokes, vasculitic skin lesions, and/or polyarteritis nodosa. Transfusion-dependent anemia and severe neutropenia are uncommon manifestations.

TNF inhibition under expert supervision is highly effective in preventing stroke.[19] Hematopoietic stem cell transplantation may be curative, both for cytopenias and vascular manifestations.

GENOME SEQUENCING AND THE DISCOVERY OF NEW AUTOINFLAMMATORY SYNDROMES AND INNATE IMMUNE PATHWAYS

A major attraction of the concept of the autoinflammatory diseases has been the molecular explication of numerous inborn errors of inflammation, an enterprise that has converged with the delineation of the innate immune system (Chapter 35). With advances in genome sequencing, the number of defined autoinflammatory diseases that are associated with dramatically elevated levels of total and free IL-18 in the blood has increased rapidly. Recently defined conditions include autoinflammatory periodic fever, immunodeficiency, and thrombocytopenia (PFIT), which is caused by mutations in the actin-regulatory gene *WDR1;* neonatal-onset pancytopenia, autoinflammation, rash, and hemophagocytic lymphohistiocytosis (NOCARH syndrome),[20] which is caused by mutations in *CDC42* that activate the pyrin inflammasome; and mutations in *MEFV,* which encodes pyrin. Taken together, these findings point to a poorly understood aspect of inflammasome activation that may be amenable to therapies targeting IL-18.

Other recent genomic discoveries implicate the cell death pathways of apoptosis and necroptosis in two different autoinflammatory disorders caused by mutations in *RIPK1* and *TBK1*.[21] Gain-of-function mutations in *ALPK1,* encoding a novel innate immune sensor for seven carbon sugars (which are made by gram-negative bacteria but not by mammals), cause an autoinflammatory syndrome characterized by retinal dystrophy, optic nerve edema, splenomegaly, anhidrosis, and migraine headache (ROSAH).[22] Genomic sequencing of children carrying the diagnosis of systemic-onset juvenile idiopathic arthritis has identified *LACC1* as an important regulator of immunometabolic function in macrophages, and genomic sequencing of patients with a form of chronic recurrent multifocal osteomyelitis has identified *LPIN2* as an important regulator of osteoclast differentiation in M2 macrophages.[23] Gain-of-function mutations in *PLCG2,* which encodes the phospholipase Cγ2 enzyme that has essential functions in B-cell receptor and Fc receptor signaling, cause a dominantly inherited autoinflammatory syndrome characterized by blistering skin lesions, bronchiolitis, arthralgia, ocular inflammation, and enterocolitis in the absence of autoantibodies.

SOMATIC MUTATION AND LATE-ONSET AUTOINFLAMMATORY DISEASE

An autoinflammatory disorder caused by myeloid-restricted somatic mutations in *UBA1*, which is one of the critical regulators of ubiquitylation in all cells,[24] is manifested by fever, relapsing polychondritis (usually affecting the nasal and/or auricular cartilage but sparing the trachea), neutrophilic dermatosis, medium-vessel vasculitis, pulmonary infiltrates, neutrophilic alveolitis, venous thromboembolism, macrocytic anemia, vacuoles in myeloid precursor cells in the marrow, and hypercytokinemia. Based on the demonstration of somatic *UBA1* mutations, this condition is termed VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) syndrome. Because *UBA1* is encoded on the X-chromosome, VEXAS syndrome is observed almost exclusively in men, usually over age 40 years. Given the high mortality rate, early allogeneic stem cell transplantation may be advisable.

Adult-onset syndromes resembling the inherited versions of both the cryopyrinopathies and TRAPS are caused by somatic mutations in *NLRP3* and *TNFRSF1A,* respectively. The discovery of these syndromes raises the possibility of somatic mutations in other adult-onset rheumatic diseases and emphasizes the likelihood of other genetic diagnoses that cut across the boundaries of current clinical syndromes.

241 OSTEOARTHRITIS

DAVID J. HUNTER

DEFINITION

Osteoarthritis is characterized by failed repair of synovial joint tissues after intra-articular stress. The resulting breakdown of cartilage and bone can lead to symptoms of pain, stiffness, and functional disability. However, synovial joint pathology and structural changes on imaging studies may correlate poorly with patient-reported symptoms.

EPIDEMIOLOGY

Osteoarthritis is a highly prevalent, disabling disease that affects more than 500 million people worldwide, with women disproportionately affected.[1] The

ABSTRACT

Osteoarthritis is a heterogeneous syndrome and an increasingly prevalent source of disability. The combined impacts of aging, obesity, and increasing rates of joint injury are increasing the numbers of people with this disease. Important insights are clarifying the pathogenesis, etiology, and sources of pain. Diagnosis is based on clinical presentation with little need for imaging or laboratory investigation. Management should be individually tailored and focus on core treatments, including self-management, exercise, and maintaining a healthy weight.

management

incidence of osteoarthritis increases rapidly between ages 50 and 75 years (Fig. 241-1).[2] The age-standardized incidence and prevalence are also increasing, and an estimated 25% of the total U.S. adult population will have physician-diagnosed osteoarthritis by the year 2040.

In part as a consequence of aging, obesity, and joint injury, the number of people affected by osteoarthritis globally rose by 48% from 1990 to 2019, and osteoarthritis is now the 15th highest cause of years lived with disability worldwide.[3] Of people affected by osteoarthritis, 80% suffer from limitations in movement and 25% have difficulty in performing their major activities of daily living.[4] Osteoarthritis of the knee accounts for approximately 85% of the burden attributable to osteoarthritis. The lifetime risk of having symptomatic knee osteoarthritis is about 40% in men and 47% in women, and the risk increases to 60% among persons above a healthy weight.[5]

PATHOBIOLOGY

Osteoarthritis results in structural alterations in the hyaline articular cartilage, subchondral bone, synovium, ligaments, capsule, and periarticular muscles. This dynamic process involves a range of factors, including mechanical, inflammatory, and metabolic pathways, which create an imbalance between repair and destruction of joint tissues and ultimately lead to failure of the synovial joint.

The pathologic changes of osteoarthritis include alterations in most of the structures of synovial joint tissue.[6] Compositional changes in cartilage (initially proteoglycan attracts water, thereby leading to swelling of articular cartilage and then disruption of the type 2 collagen matrix) alter its material properties and increase its susceptibility to disruption by physical forces. Erosions occur at the cartilage surface, and then deep cartilage fissures are accompanied by the expansion of the calcified cartilage zone. Hypertrophic chondrocytes appear and exhibit increased synthetic activity, thereby reflecting an attempt at repair, and they generate matrix degradation products and proinflammatory mediators that further deregulate chondrocytic function and act on the adjacent synovium to stimulate proliferative and proinflammatory responses.[7] Breakdown products of cartilage and bone evoke a synovial inflammatory response, which becomes both hyperplastic (increased numbers of synovial lining cells) and hypertrophic (small villi or folds developing in the membrane, with infiltration of macrophages, lymphocytes, and plasma cells) and is accompanied by an increase in the vascularity in the subintimal layer.

In the subchondral bone, increased bone turnover and vascular invasion from the subchondral bone damage cartilage. The bone remodeling and repair is also associated with the development of subchondral bone marrow lesions, which are associated with both pain and progressive disease. The evolution of these lesions can lead to the formation of focal necrosis and subchondral cysts. Reactivation of endochondral ossification leads to osteophytes, which develop at the joint margins and are strongly affected by inflammatory biologic factors, overload, and abnormal joint kinematics.[8] Meniscal (myxoid degeneration, tears, and maceration) and ligamentous abnormalities are common, as are periarticular muscle atrophy and weakness.

Mechanics versus Inflammation

Mechanical load is the primary risk factor responsible for the development of osteoarthritis when excessive mechanical strain is transmitted through a normal joint (obesity, joint malalignment, occupational risk) or when a normal load traverses a joint that has lost its mechanical protection because of disruption of ligaments, meniscal damage, or muscle weakness).[9] This altered mechanical load induces activation of inflammatory signaling pathways to drive the process of joint breakdown (E-Fig. 241-1). This inflammation occurs locally within the tissues, including cartilage and subchondral bone, with synovitis and osteophytes. The process is frequently driven systemically by obesity-related inflammation.

Risk Factors

For most persons affected by osteoarthritis, its development can be linked to multiple risk factors that can be grouped either into local/systemic risk factors, which may be modifiable or nonmodifiable (Fig. 241-2). Potentially modifiable risk factors include increased body weight, joint malalignment, muscle weakness, a sedentary lifestyle, occupational exposure, and athletic injuries. In contrast, nonmodifiable risk factors include age, ethnicity, genetics, prior injury, and sex.

The genetic contribution to osteoarthritis varies by joint and is stronger for the hand than for the knee. Except for monogenetic disorders such as

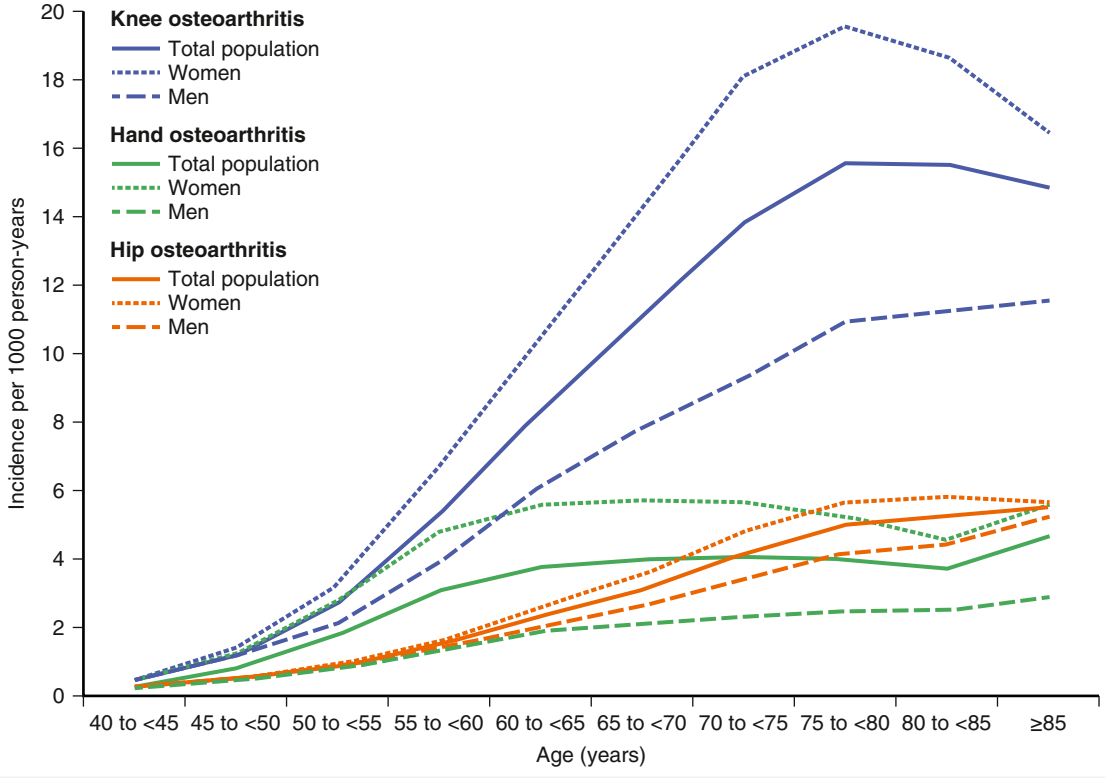

FIGURE 241-1. Incidence of osteoarthritis. Age and sex-specific incidence rates (per 1000 person-years) of knee osteoarthritis *(blue)*, hip osteoarthritis *(orange)*, and hand osteoarthritis *(green)*. Long dashed line = men; short dashed line = women; solid line = all population. (From Prieto-Alhambra D, Judge A, Javaid MK, et al. Incidence and risk factors for clinically diagnosed knee, hip and hand osteoarthritis: influences of age, gender and osteoarthritis affecting other joints. *Ann Rheum Dis*. 2014;73:1659-1664.)

(From Hunter DJ, Bierma-Zeinstra S. Osteoarthritis. *Lancet*. 2019;393:1745-1759.)

chondrodysplasia, the genetic contribution to osteoarthritis is polygenic, and over 100 polymorphic DNA variants with small effects have been identified to date. These genetic variants account for over 20% of the heritability of osteoarthritis and largely map to non-protein coding regions of the genome that might regulate expression of target genes.[10] These targets include extracellular signaling molecules, intracellular enzymes, transcription factors, and cytoskeletal proteins. A number of these risk variants relate to epigenetic factors, in particular DNA methylation, whereas other variants appear to have been selected as humans adapted to bipedalism.

Phenotypes and Endotypes

Osteoarthritis is an umbrella diagnosis referring to a multifaceted and heterogeneous syndrome rather than one single disease. The commonly described identifiable predisposing factors for most forms of osteoarthritis include hormonal changes (e.g., estrogen deficiency), metabolic syndrome, post-traumatic injury, mechanical overload, inflammatory responses, genetic predisposition, and aging (E-Fig. 241-2).

Etiology of Pain

Pain is the dominant presenting symptom and typically the main driver for clinical decision-making in patients with osteoarthritis. The most useful framework for understanding pain is the biopsychosocial model (E-Fig. 241-3; Chapter 26), including psychological factors and socioeconomic factors, in contrast to the traditional biomedical approach, in which the major focus usually is on joint pathology. The degree of structural osteoarthritis bears at best a moderate association with the severity of pain.

Pain in osteoarthritis is classically considered nociceptive pain, described as mechanical in nature and arising from the loading of a damaged joint. In addition to peripheral nociceptive pain mechanisms, pain sensitization by means of neuropathic pain mechanisms and/or central pain mechanisms seem to be present in a substantial proportion of people with osteoarthritis.[11] This sensitization of central pathways influences the perception of pain, which shows marked heterogeneity among patients. People who have osteoarthritis and who demonstrate alterations in neurophysiologic nociceptive signal processing often respond poorly to standard treatments. Nevertheless, removing the stimulus through nerve block or joint replacement can relieve pain, thereby suggesting that pain signaling is dependent on peripheral triggers, presumably through joint nociceptors that remain responsive to ongoing tissue injury or inflammation.

CLINICAL MANIFESTATIONS

Symptoms

Osteoarthritis typically has a very gradual onset over a number of years, with pain as the key feature. The typically slow, insidious structural progression of osteoarthritis may be punctuated with intermittent periods of increased disease activity.[12] The natural history of osteoarthritis is highly variable and usually evolves over decades (E-Fig. 241-4).

Pain is usually mechanical in nature, occurs with activity, and is often worse towards the end of the day. In more advanced disease, pain may be present at rest. Osteoarthritis can affect any synovial joint in the body but most commonly affects the hands, knees, spine, hips, and feet.

Other symptoms include joint stiffness that is usually localized to the involved joint, rarely persists for more than 15 to 30 minutes, and is most noticeable when first mobilizing after a period of inactivity. Patients may also complain of crepitus or grating that they can feel and hear as their joints move. As the disease progresses, patients may notice limitation of joint range of motion and associated difficulty performing activities such as opening jars for hand osteoarthritis, going up and down stairs or rising from a chair for knee osteoarthritis, or getting in and out of the car or putting shoes and socks on for hip osteoarthritis. Other local symptoms include catching or locking, especially around the knee, that can be associated with falls.

Signs

In the early stages of the disease, patients may have very few visible signs. As the disease progresses, joints may be tender to palpation along the respective joint line. With time, range of motion is lost and crepitus might be palpable on movement of the joint, most prominently under the patella on flexion and extension of the knee. Joint swelling may be palpable, both bony swelling as a result of osteophytes and soft tissue swelling due to joint effusion. Ongoing damage to the joint can lead to alterations in alignment, along with muscle weakness and atrophy. Additional joint-specific features that may be present on examination of the knee include deformity (varus, fixed flexion, or less commonly valgus for the knee), instability on ligament testing, periarticular tenderness, and pain on patellofemoral compression. Early physical signs of osteoarthritis in the hip include restriction of internal rotation, with pain occurring at the end of the range of motion.

DIAGNOSIS

The diagnosis of osteoarthritis is clinical based upon symptoms (pain, brief morning stiffness, and functional limitation) and physical examination (crepitus, restricted or painful movement, joint tenderness, and bony enlargement).[13] Plain radiographs are not necessary but can be considered for atypical presentations or for diagnostic clarity.

Presenting features that might lead towards consideration of an alternative or additional diagnosis include prolonged morning joint-related stiffness (rheumatoid arthritis; Chapter 242), a recent history of trauma, the presence of a swollen hot joint (crystal deposition disease [Chapter 252] or infection

TABLE 241-1 HOLISTIC ASSESSMENT OF PATIENTS WITH OSTEOARTHRITIS

Social factors: impact of the condition on activities of daily living, relationships, quality of life, and recreational and occupational activities
Health beliefs and concerns: previous knowledge of osteoarthritis; expectations of treatment; understanding of treatment options including benefits and harms
Psychological factors: screen for depression; stresses in life; mood
Attitudes to physical activity and exercise: concerns; restrictions; access to appropriate facilities
Pain assessment: nature of pain, other sites of pain, self-help strategies; use of analgesics, doses, frequency and side effects; current understanding about persistent pain
Functional capacity: such as walking ability, stair climbing, sit-to-stand, balance
Presence of support: concerns and expectations of carers (including family and friends); isolation issues
Influence of comorbidities: interaction of two or more morbidities; risk of falls
Modifiable risk factors: overweight/obesity; joint alignment; and injury/buckling

Reproduced with permission from The Royal Australian College of General Practitioners from: Guideline for the management of knee and hip osteoarthritis. Chapter 1.6: Assessment of people with hip and/or knee OA. Section 1.6.1: Holistic assessment. 2nd edn. East Melbourne, Vic: RACGP, 2018; p. 15. Available at www.racgp.org.au/getattachment/71ab5b77-afdf-4b01-90c3-04f61a910be6/Guideline-for-the-management-of-knee-and-hip-osteoarthritis.aspx.

[Chapter 251]), or rapid worsening of symptoms. Laboratory tests (e.g., rheumatoid factor, synovial fluid aspirate for crystal confirmation, erythrocyte sedimentation rate or C-reactive protein) may be helpful to confirm or exclude coexistent inflammatory disease (e.g., rheumatoid arthritis, calcium pyrophosphate crystal deposition, gout) in patients with suggestive symptoms or signs. However, routine laboratory tests on blood, urine, or synovial fluid are not required to diagnose osteoarthritis.

If a palpable moderate to large effusion is present, synovial fluid should be aspirated and analyzed to exclude inflammatory disease and to identify urate and calcium pyrophosphate crystals. In osteoarthritis, synovial fluid is typically noninflammatory with fewer than 2000 leucocytes/μL. Basic calcium phosphate crystals are often present.

Holistic Evaluation

Because osteoarthritis is so common and is a chronic disease, patients benefit from a holistic assessment. (Table 241-1).

Imaging

Imaging is limited to atypical presentations, when the clinical diagnosis is uncertain, when other diagnoses are suspected, or when interventional therapy is being planned. Many of the structural abnormalities seen on imaging are very common in older populations, for example, meniscal tears are an almost universal finding in people with osteoarthritis and are typically just age-related abnormalities and not related to symptoms. Radiographic changes and symptoms are poorly correlated with each other in osteoarthritis, and the common occurrence of structural abnormalities in older adults must be considered when evaluating radiographic computed tomographic scan or magnetic resonance images.[14] Imaging also can lead to increased use of unnecessary or harmful interventions.

TREATMENT

The management of osteoarthritis is complex and challenging, but a careful evaluation can help guide an individual treatment plan (Table 241-2).[15] Clinicians should prioritize interventions that are safe, accessible, and cost-effective.

Active, nonpharmacologic interventions are the mainstay of management and should be tried first, followed by or in concert with medications to relieve pain when necessary.[16] These core treatments include education, weight management,[A1] promotion of physical activity,[A2,A3] therapeutic exercises, and help in changing behavior.[A4] These treatments may be facilitated by providing a referral to appropriate health care professionals, including physiotherapists and dieticians.

Physical activity usually refers to everyday exercise (e.g., walking, cycling, swimming), whereas therapeutic exercise (Table 241-3) refers to planned, structured, repetitive activities undertaken to improve osteoarthritis management. Guidelines strongly recommend weight loss for anyone with a BMI of 25 kg/m^2 or higher. The recommended starting point is to lose 5 to 10% of body weight, but greater weight loss leads to greater benefits for both pain and function.

Analgesic medications can be used following or in concert with core treatments for patients with persistent or severe symptoms. Nonsteroidal anti-inflammatory drugs (NSAIDS) are usually advocated as the first-line therapy,[A5] and topical over-the-counter NSAIDs are preferred over systemic treatments (Table 26-4) owing to safety concerns. For patients who require oral analgesia, the central tenant is usually the lowest dose for the shortest duration possible. Low-dose (10 mg daily) oral prednisolone is safe and efficacious for short term (6 weeks) treatment, but symptoms return rapidly when it is discontinued,[A6] and physical therapy appears to be better than standard glucocorticoid injections for relieving pain and preserving function in patients with osteoarthritis of the knee.[A7] Physicians should avoid reliance on glucosamine, chondroitin

TABLE 241-2 COMPREHENSIVE ASSESSMENT OF PATIENTS WITH OSTEOARTHRITIS OF THE KNEE AND PRACTICAL IMPLICATIONS FOR MANAGEMENT

ASSESSMENT ELEMENTS	PRACTICAL IMPLICATIONS
Joint symptoms and signs such as joint pain, giving way, stiffness, locking or catching, effusion, diminished range of motion, tenderness on palpation, joint laxity, abnormal knee alignment in standing	Helps with differential diagnosis and establishes whether radiography and magnetic resonance imaging are needed. Neuropathic symptoms (shooting, burning pain, and pins and needles) may indicate need for a centrally active agent. Changes in pain allow assessment of response to treatment. If the patient has disabling locking or catching, consider orthopaedic referral. If the patient has giving way and laxity, consider a gait aid, physiotherapy for muscle strengthening, and referral to an orthotist for bracing. If knee malalignment is present, bracing may be beneficial
Comorbid conditions such as cardiovascular disease, diabetes, peptic ulcer, renal, liver disease, depression	Influence contraindications and precautions for treatment, in particular prescription of drugs
Functional ability, impaired activities of daily living (such as walking, stair climbing, sit to stand, balance) and history of falls	If difficulty with walking, function, balance, or if more than 1 fall in past 12 months, consider gait aid, attention to footwear, and referral to a physiotherapist for treatment including exercise prescription and manual therapy. If a varus thrust is seen during walking (visible dynamic worsening or varus alignment during stance phase), consider referral to a physiotherapist for exercise program and possibly to an orthotist for bracing
Muscle mass and strength, particularly of the quadriceps	If weak, prescribe muscle strengthening exercises; consider referral to a physiotherapist or exercise specialist
Foot posture	If abnormal, consider referral to a podiatrist for orthotics and footwear advice
Psychosocial factors, such as mood disorders (depression and anxiety), abnormal sleep, poor social support, inability to cope, reduced participation in leisure activities, relationships, and difficulties at work	If mood disorder present, consider referral to a psychologist or psychiatrist or prescription of antidepressants (Table 362-5). If difficulty coping or participating, consider referral to appropriate allied health practitioner (such as a psychologist, occupational therapist, or social worker) or relevant self-help groups for peer support
Patient's knowledge, expectations, and goals	Careful assessment can guide a patient-centered approach to management and communication, tailored to patient's needs and goals. Ensure that the patient understands the disease process, has realistic expectations, and participates in treatment decision-making by providing education, information, and resources. Consider referral to a self management program
Overweight or obesity (weight, body mass index, and waist girth)	If body mass index >25 or waist >80 cm in women or >94 cm in men, counsel about weight loss (Chapter 201) through both diet (Chapter 13) and exercise (Chapter 14: aerobic and strengthening). If possible, refer to a dietitian for nutritional assessment and weight loss support (Chapter 201). Weight loss program should aim for a 5 to 10% reduction

From Bennell KL, Hunter DJ, Hinman RS. Management of osteoarthritis of the knee. *BMJ*. 2012;345:e4934.

TABLE 241-3 EXAMPLES OF EXERCISES AND PHYSICAL ACTIVITIES FOR IMPROVING OSTEOARTHRITIS-RELATED PAIN AND FUNCTION

TYPE OF ACTIVITY	HAND	KNEE	HIP	DESCRIPTION
General physical activity	+	+	+	Many sports and everyday activities can provide aerobic exercise and improve general physical activity levels. Examples include walking or cycling for recreation or to work, gardening, dancing, walking a dog, or playing with children
Aerobic exercise	NA	+	+	Any type of exercise that raises heart rate is recommended. Land-based examples of aerobic exercises include running or jogging, cycling (stationary or moving), and power walking
Strengthening	+	+	+	Exercises to strengthen specific muscles around the affected joint(s) is recommended. Strengthening can be undertaken using body weight exercises or seated exercises (e.g., squats or seated knee extension), or using free weights, resistance machines, or resistance bands
Neuromuscular and balance exercises	NA	+	+	Neuromuscular and balance exercises specifically targeted to the ability to control and stabilize body position and to improve balance and coordination. Examples include walking on soft surfaces, wobble boards, and single leg balancing
Tai chi and yoga	NA	+	+	Tai chi and yoga are examples of mind-body exercises (Chapter 30) because they have a whole-body focus (e.g., a focus on breathing and coordinated or postured movements) and an emphasis on mindfulness (e.g., meditation and focus)
Joint mobility and stability	+	+	+	Exercises to improve joint mobility and stability are recommended. Exercises for the hand should be aimed at improving joint mobility, muscle strength, and thumb base stability, and they should be tailored for the specific joint(s)
Water-based exercises	NA	+	+	Water-based therapies can include aerobic fitness exercises (e.g., aqua aerobics, swimming, deep water running, and water-based sports) and/or exercises for enhancing the strength and range of motion of a joint in a low-impact environment (e.g., hydrotherapy)

Adapted from Bowden JL, Hunter DJ, Deveza LA, et al. Core and adjunctive interventions for osteoarthritis: efficacy and models for implementation. *Nat Rev Rheumatol*. 2020;16:434-447.

supplements, opioids, viscosupplements,[A8] or repeated injections of corticosteroids, which have at most very modest benefit in some patients.[A9,A10] Injections of platelet-rich plasma are not of documented benefit.[A11,A12]

Referral of patients with end-stage osteoarthritis to an orthopedic surgeon should be considered when all appropriate conservative options, delivered for a reasonable period, have failed (Chapter 255). Symptoms that warrant surgical evaluation include joint pain that disrupts normal sleep patterns, severely reduces walking distance, markedly restricts activities of daily living, or significantly reduces quality of life.

Newer Treatment Options

An area of active research focuses on developing disease-modifying drugs[17] that might alter the natural history of osteoarthritis by arresting structural damage. A potential promising option may be the intraarticular injection of sprifermin, which is a recombinant human fibroblast growth factor, that can increase the thickness of femorotibial cartilage but so far without obvious clinical benefits.[A13,A14]

PREVENTION

Since no cure exists for osteoarthritis, public health measures to prevent disease are of great interest.[18] Two major approaches are to prevent joint injury and to reduce weight in overweight or obese individuals. For example, a reduction in body weight from obese (body mass index [BMI] ≥30 kg/m^2) to overweight (BMI ≥26 and <30 kg/m^2) or from overweight to normal (BMI <26 kg/m^2) reduces the incidence of symptomatic knee osteoarthritis by about 20% in men and one third in women. A 5-kg or 5% weight loss can reduce incident clinical knee osteoarthritis from 21 to 7% over a 6 to 7 year follow-up.

An anterior cruciate ligament injury strongly correlates with the later development of knee osteoarthritis. Prevention programs that focus on sports-specific movements and tasks can decrease injury rates, including anterior cruciate ligament injuries, by 50 to 80%.[19]

PROGNOSIS

Osteoarthritis is characterized by marked short fluctuations, which vary in frequency, intensity, and duration and are the prime drivers of disability and health care utilization. However, the vast majority (about 85%) of individuals have a relatively flat symptomatic trajectory over years to decades.[20] Only 7% of people with knee osteoarthritis have a trajectory characterized by worsening, 85% are stable, and 8% experience a reduction in pain.

Surgical rates continue to increase, with a projected increase in total knee replacement volume of about 50% from 2021 to 2050 in the United States. The presence of comorbid conditions, including depression and lower educational level, are predictors of worsening pain trajectory. The obesity and physical limitations associated with osteoarthritis likely explain why premature mortality is increased by 20 to 25% in patients with osteoarthritis of the knee and by 20% in patients with osteoarthritis of the hip.[21]

BURSITIS, TENDINOPATHY, OTHER PERIARTICULAR DISORDERS, AND SPORTS MEDICINE

JOSEPH J. BIUNDO AND JUAN J. CANOSO

DEFINITION

An array of painful and sometimes disabling musculoskeletal syndromes exist that are not articular in origin but arise from tendons, ligaments, enthesis, and bursae. These conditions are referred to by various names, in addition to *tendinosis, enthesopathy,* and *bursitis,* including the terms *nonarticular rheumatism, soft tissue diseases, regional rheumatic pain syndromes,* and *repetitive use syndromes* (Table 242-1). These entities are often ignored, misdiagnosed as arthritis, or attributed to the aging process. Awareness of the existence of these conditions and knowledge of basic musculoskeletal anatomy (Figs. 242-1 and 242-2) are the fundamental requirements for diagnosis. This knowledge is coupled with brief but specific physical diagnosis techniques. The accurate diagnosis and successful treatment of these conditions is gratifying to the clinician because many people can be relieved of their chronic painful syndromes.

Various terms regarding tendon injuries are used and may be confusing. The main term used is *tendinitis,* but *tendinosis* is the correct terminology because there are degenerative changes in the tendon but very few inflammatory cells. In addition, fatty mucoid degeneration and hyaline features occur in these tendon syndromes. Also, tendons may *rupture* or *tear,* partially or completely.

TABLE 242-1 NONARTICULAR PAIN SYNDROMES, BY REGION

SHOULDER
Rotator cuff tendinosis; rotator cuff tear
Bicipital tendinosis; biceps tendon tear
Subacromial bursitis
Adhesive capsulitis (frozen shoulder)
ELBOW
Olecranon bursitis
Medial epicondylalgia
Lateral epicondylalgia
WRIST AND HAND
De Quervain tenosinovitis
Trigger finger
Digital flexor tenosynovitis
Ganglia (dorsal and volar wrist, finger, etc.)
HIP
Greater trochanter pain syndrome (gluteus medius and minimus tendinosis and tear; trochanteric bursitis)
Iliopsoas bursitis
Ischial bursitis
Coccydynia
KNEE
Prepatellar bursitis
Infrapatellar bursitis
Pes anserine syndrome
Iliotibial band syndrome
Popliteal (Baker) cyst
Quadriceps tendon tear
Patellar tendinosis and tear
Hoffa syndrome
ANKLE AND FOOT
Achilles tendinosis, insertional and mid-tendon
Achilles tendon tear
Retrocalcaneal bursitis
Posterior tibial tendinosis and tenosynovitis
Posterior tibial tendon tear
Plantar fasciopathy (fasciitis)
Morton neuroma

The terms *tenosynovitis* and *peritendinitis* refer to an inflammatory response of the tenosynovium, such as in rheumatoid arthritis. However, tenovaginosis and peritendinosis are more appropriate terms in oversuse conditions. Tendinosis may occur when the tendon repeatedly bears more load than it can withstand. This may result from excessively high loads across normal tendons or from normal loads across degenerated tendons. In addition to load and repetitiveness, tendon changes resulting from immobility and from aging may play a role, as may the use of certain medications such as fluoroquinolones and corticosteroids.

Bursae are closed sacs lined by a synovial membrane, often discontinuous, and serve to promote smooth tissue gliding between tendon and bone, tendon and tendon, or bone and skin. A bursa can become inflamed from trauma or overuse or become infected, thereby producing a bursitis. Bursitis is typically associated with pain and swelling of the bursa.

EPIDEMIOLOGY

The incidence and prevalence of the nonarticular syndromes are high. They are more common than rheumatoid arthritis and systemic lupus erythematosus combined. For example, the incidence of shoulder pain, largely a result of rotator cuff tendinosis and rotator cuff tear, is approximately 20% in a population older than 70 years of age.

DIAGNOSIS

A precise history is needed to identify the conditions present, and more than one syndrome can occur concomitantly. A working knowledge of regional anatomy and an approach that uses a regional differential diagnosis will help in obtaining a specific diagnosis. A complete neuromusculoskeletal examination should be performed, emphasizing careful palpation, passive range of motion (ROM), and active ROM alone or sometimes with resistance. Systemic and infectious causes must be considered. Diagnostic ultrasonography is very useful in confirming a musculoskeletal diagnosis.[I] Magnetic resonance imaging (MRI) is also sometimes useful in confirming a diagnosis.

TREATMENT

The causative aspects of symptoms should be evaluated, and activity should be modified as needed. Provided that the excessive load that caused the condition is reduced, most tendinopathies tend to improve with conservative therapy such as nonsteroidal anti-inflammatory drugs (NSAIDs; Table 26-4), relative rest of the injured site, stretching and strengthening exercises, friction massage, and use of modalities such as heat, ice, and ultrasound. The goals of therapeutic exercise are to increase flexibility by stretching, increase muscle strength by resistive exercises, and improve muscle endurance by some repetitive regimen.

Splinting, corticosteroid injections (given as the equivalent of 40 mg/mL of methylprednisolone acetate), and even surgery are options for more severe or recalcitrant symptoms.[A1,A2] Caution should be exerted in performing corticosteroid injections; the injections should not be placed into the tendon proper, but rather into the peritendinous sheath. The injected solution should be placed beneath the subcutaneous tissue, to avoid skin and subcutaneous fat atrophy and skin depigmentation, and injections should not be given too frequently, to avoid the possibility of weakening and rupture of the tendon. The accuracy of injections may be improved with concomitant use of diagnostic ultrasonography to assist with determining the correct needle site.

SPORTS MEDICINE INJURIES

An overlap exists between commonly occurring conditions (e.g., tendinosis, enthesopathy, bursitis) and conditions attributed to specific sports injuries (Table 242-2). For example, lateral epicondylalgia, frequently referred to as *tennis elbow,* occurs more commonly secondary to non–sports-related causes. In contradistinction, iliotibial band syndrome is usually related to sports. Other entities that occur more often in relation to sports include ligamentous knee injuries, patellar tendinosis, ankle sprains, turf toe, and acromioclavicular separations. It is important in both categories to know the anatomy and biomechanics of the condition so the problem can be diagnosed and treated appropriately. Sports-related injuries are helped with the classic RICE treatment, consisting of *r*est, *i*ce, *c*ompression, and *e*levation. Often, anti-inflammatory and analgesic drugs are used. However, corticosteroid injections are less often used for athletic injuries than in routine cases of tendinosis and bursitis because of fear of weakening the involved structures.

DISORDERS OF THE SHOULDER REGION

Shoulder pain is one of the most common musculoskeletal complaints in people older than 40 years of age. In younger people, athletic injuries are a frequent source of such pain.

ABSTRACT

Musculoskeletal pain syndromes involving the shoulder, elbow, wrist, hand, hip, knee, ankle, and foot are common but unfortunately are often overlooked by primary care physicians. These disorders are often ignored or misdiagnosed as arthritis by nonspecialty physicians. The accurate diagnosis, based on functional musculoskeletal anatomy, and successful treatment of these painful and sometimes disabling conditions are gratifying to the patient and clinician alike.

A,** Anterior aspect of the hip joint and bony structures. **B,** Relationship of the distended iliopsoas, trochanteric, and ischiogluteal bursae (shown in *blue*) to the hip joint and adjacent structures. (From Polley HF, Hunder GG, eds. *Rheumatologic Interviewing and Physical Examination of the Joints*, 2nd ed. Philadelphia: WB Saunders; 1978:183.)

Rotator Cuff Impingement

Rotator cuff tendinosis, or impingement syndrome, is the most common cause of shoulder pain. Tendinosis (and not bursitis) is the primary cause of pain, but secondary involvement of the subacromial bursa occurs in some cases. The condition may be acute or chronic and may or may not be associated with calcific deposits within the tendon. The key finding is pain in the rotator cuff on active abduction, especially between 60 and 120 degrees, and sometimes when lowering the arm. In more severe cases, pain may begin on initial abduction and continue throughout the ROM. Typically, chronic rotator cuff tendinosis manifests as an ache in the shoulder, usually over the lateral deltoid, and occurs with various movements, especially abduction, internal rotation, and the resisted action of the involved muscle(s). Other symptoms include difficulty in dressing oneself and night pain because of difficulty in positioning the shoulders. The physical findings include pain and loss of active abduction and internal rotation, less pain on passive motion, tenderness of the area of supraspinatus insertion, and a positive impingement (Neer) sign (Fig. 242-3), which is pain occurring in forced flexion. The causes of rotator cuff tendinosis are multifactorial, but normal wear and relative overuse, especially from overhead activity that causes impingement of the rotator cuff, are commonly implicated.

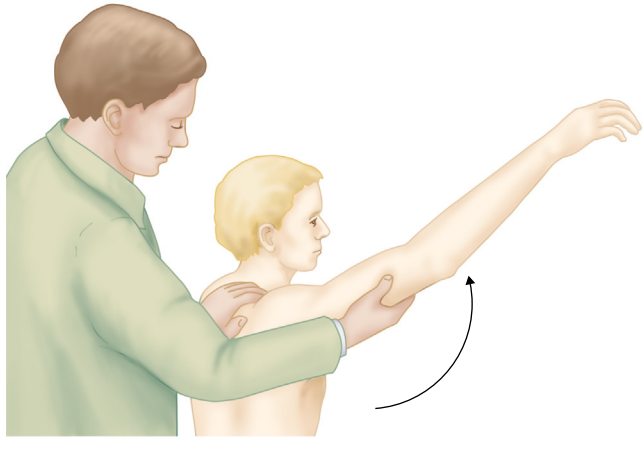

FIGURE 242-3. **The impingement sign is elicited by forced forward elevation of the arm.** Pain results as the greater tuberosity impinges on the acromion. The examiner's hand prevents scapular rotation. This maneuver may be positive in other periarticular disorders. (From Neer CS II. Impingement lesions. *Clin Orthop*. 1983;173:70-77.)

TABLE 242-2 ADDITIONAL SPORTS-RELATED CONDITIONS

SHOULDER
Acromioclavicular separation
Glenoid labial tear (SLAP lesion)
Glenohumeral instability with dislocation
ELBOW
Triceps tendinopathy
Little League elbow (apophysitis)
Distal biceps tendinosis
WRIST AND HAND
Gamekeeper's thumb (skier's thumb)
Mallet finger (baseball finger)
Extensor carpi ulnaris tendinitis
Rupture of flexor digitorum profundus tendon
Injury to triangular fibrocartilage
HIP
Adductor strain (groin pull)
Hip pointer
Hamstring strain
KNEE
Anterior cruciate tear
Posterior cruciate tear
Medial collateral ligament tear/strain
Lateral collateral ligament tear/strain
Popliteal tendinitis
Medial and lateral meniscal tears
Patellar tendinitis
Iliotibial band syndrome
ANKLE AND FOOT
Ankle sprain
Turf toe
Stress fracture

SLAP lesion = superior labrum anterior and posterior lesion.

TREATMENT

Treatment consists of rest and modalities such as hot packs, ultrasound, or cold applications, with specific range of motion exercises as soon as tolerated.[2] NSAIDs (Table 26-4) are often beneficial. Injection of a depot corticosteroid, such as 1 mL of a 40 mg/mL concentration of methylprednisolone acetate into the subacromial bursa, the floor of which is contiguous with the rotator cuff, can provide improvement for up to 8 weeks but probably not long-term benefit.[A3–A5] Extracorporeal shock wave therapy can be beneficial for chronic calcific tendinitis, but surgery is of limited benefit.[A6]

Rotator Cuff Tear

In a rotator cuff tear, an acute tear after trauma is usually easily recognized. The trauma may be superimposed on an already degenerative and possibly even partially torn cuff. In cases of trauma resulting in a ruptured cuff, fracture of the humeral head and dislocation of the joint also should be considered. However, most patients with a tear recall no trauma. In these cases, degeneration of the rotator cuff occurs gradually, resulting ultimately in a complete tear.

MR is the preferred imaging test.[3] Rotator cuff tears are classified as small (≤1 cm), medium (1 to 3 cm), large (3 to 5 cm), or massive (>5 cm). Shoulder pain, weakness on abduction, and loss of motion occur in varying degrees, ranging from severe pain and mild weakness to no pain and marked weakness. A positive drop-arm sign with inability to maintain actively 90 degrees of passive shoulder abduction may be present in patients with large or massive tears.

TREATMENT

Small complete tears and incomplete tears of the rotator cuff are treated conservatively with rest, physical therapy, and NSAIDs.[4] Although its role has not yet been established by careful studies, a subacromial injection of a corticosteroid, such as 1 mL of a 40 mg/mL concentration of methylprednisolone acetate, may relieve pain. Surgical repair may be indicated in younger patients.[A7]

Bicipital Tendinosis

Bicipital tendinosis is manifested by pain, most often in the anterior region of the shoulder and occasionally more diffusely.[5] The pain may be acute but is usually chronic and is related to impingement of the biceps tendon by the acromion. Tenosynovitis of the long head of the biceps is present, and the tendon may be frayed and fibrotic. Palpation over the bicipital groove reveals localized tenderness. The patient's response should be compared with the response to palpation of the opposite side (i.e., tendon with normal tenderness). Pain may be reproduced over the bicipital tendon in some cases by supination of the forearm against resistance (Yergason sign), shoulder flexion against resistance (Speeds test), or extension of the shoulder. Rupture of the biceps tendon can occur at the superior edge of the bicipital groove, thereby producing a characteristic bulbous enlargement of the lateral half of the muscle.

TREATMENT

Treatment of bicipital tendinitis consists of rest, hot packs, ultrasound, and, as pain subsides, passive and then active ROM exercises. NSAIDs (Table 26-4) may be helpful, and occasionally a small amount of corticosteroid, such as 0.5 mL of a 40 mg/mL concentration of methylprednisolone acetate, carefully injected into the tendon sheath or 1 mL of a 40 mg/mL concentration of methylprednisolone acetate intra-articularly in the shoulder may be of benefit.

Frozen Shoulder

Adhesive capsulitis (frozen shoulder) is associated with generalized pain and tenderness and severe loss of active and passive motion in all planes.[6] It is rare before 40 years of age but may occur secondary to any type of shoulder problem. However, not every stiff and painful shoulder is necessarily adhesive capsulitis. Inflammatory arthritis and diabetes can cause adhesive capsulitis. Additional factors such as immobility and neglect or improper initial treatment also favor the development of a frozen shoulder. Symptoms and function are adversely affected by depression and anxiety (Chapter 362).[7] Many cases, however, are idiopathic. The joint capsule adheres to the anatomic neck, and the axillary fold binds to itself, causing restricted motion. The capsule becomes thickened and contracted. Arthrography may help confirm this diagnosis by showing a decrease in volume of the shoulder joint capsule but is usually not needed.

TREATMENT AND PROGNOSIS

Oral steroids improve pain and range of motion in the short term, but a frozen shoulder is probably best treated with a comprehensive program involving NSAIDs and corticosteroid injections of 1 mL of a 40 mg/mL concentration of methylprednisolone acetate into the glenohumeral joint and the subacromial bursa. Physical therapy consists of ice packs, ultrasound, transcutaneous electrical nerve stimulation, and gentle range of motion exercises, beginning with pendulum exercises and wall climbing with the fingers and progressing to active range of motion and strengthening exercises.[A8] Depression and anxiety may require attention (Chapter 362). In a randomized trial, manipulation under general anaesthesia supplemented by a steroid injection,[A9] arthroscopic capsular release, and structured physiotherapy were equivalently effective, but arthroscopic capsular release carried the highest risks.[A10] The duration of a frozen shoulder may last up to 9 to 12 months. In prolonged duration, manipulation of the shoulder under anesthesia can be considered.

DISORDERS OF THE ELBOW REGION

Olecranon Bursitis

Olecranon bursitis occurs frequently and involves the subcutaneous olecranon bursa, either secondary to trauma or as an idiopathic condition.[8] The bursa is characteristically swollen and tender on pressure (Fig 242-4), but pain may be minimal, and usually no motion is lost. Aspiration may yield clear or blood-tinged fluid with low viscosity or grossly hemorrhagic fluid. Inflammatory olecranon bursitis may be caused by bacterial infection, gout, rheumatoid arthritis, or calcium pyrophosphate deposition disease. Localized erythema, a scab, fissure, or previous puncture at the tip of the elbow, surrounding edema, and local tenderness all suggest septic bursitis (Chapter 251). Unlike septic arthritis, in which the elbow must be kept in semiflexion, the elbow may be brought into full passive extension in septic bursitis.

FIGURE 242-4. Olecranon bursitis in an older man. There is swelling at the elbow tip and "inverted U" furrows in the skin proximal to the bursa. For aspiration, the needle should be entered through normal lateral skin, aiming to the geometric center of the bursa to prevent leakage. The aspirated fluid was noninflammatory, sterile on culture, and contained no crystals. In septic bursitis, there may be marked swelling, even suggesting a septic elbow. However, careful passive extension is complete and painless, ruling out septic arthritis.

TREATMENT

In aseptic bursitis, aspiration alone and protection from trauma are usually sufficient to resolve the condition.[9] A small dose of a corticosteroid, such as 0.5 mL of a 40 mg/mL concentration of methylprednisolone acetate, may be injected into the bursa. Septic olecranon bursitis is treated with the appropriate antibiotics (Chapter 251) and usually one or two additional needle aspirations.

Lateral and medial epicondylalgia

Lateral epicondylalgia, or tennis elbow, is a common condition in those who overuse their arms. Localized tenderness directly over or slightly anterior to the lateral epicondyle is the hallmark of this disorder. Pain may occur during handshakes, while lifting a briefcase, or with other similar activities. Probably less than 10% of patients actually acquire lateral epicondylitis through playing tennis. Job and recreational activities, including gardening and athletics, are the usual causes. Pathologically, the condition consists of degeneration of the common extensor tendon, particularly of the extensor carpi radialis brevis tendon.

Medial epicondylitis, or golfer's elbow, which mainly involves the flexor carpi radialis, is less common and less disabling than lateral epicondylitis. Local pain and tenderness over the medial epicondyle are present, and resistance to wrist flexion exacerbates the pain.

TREATMENT

Treatment is aimed at altering activities and preventing overuse of the forearm musculature. Ice packs, heat, and NSAIDs are of some benefit.[10] A forearm brace also can be used. A local corticosteroid injection, such as 1mL of a 40 mg/mL concentration of methylprednisolone acetate with a 25-gauge needle over the epicondyle, often produces satisfactory initial relief. Isometric strengthening is important as an initial part of a rehabilitation program.[A11] Occasionally, surgery may be required for sports-related medial epicondylitis.[11]

DISORDERS OF THE WRIST AND HAND

Ganglion

A ganglion is a cystic swelling that arises from a joint or tendon sheath and occurs most commonly over the dorsum or volar aspect of the wrist. A ganglion has a focal lining, does not have a synovial derivation, and contains thick, jelly-like fluid. Ganglia apparently develop secondary to trauma or prolonged wrist extension. Usually, the only symptom is swelling, but occasionally a large ganglion produces discomfort on wrist extension or compresses a neighboring nerve. Ultrasonography is useful for making the diagnosis.

TREATMENT

Temporary immobilization with a splint or brace may be helpful. Percutaneous drainage is commonly successful, but surgery is sometimes required.[12]

De Quervain Tenosynovitis

De Quervain tenosynovitis may result from repetitive activity that involves pinching with the thumb while moving the wrist. The symptoms are pain, tenderness, and occasionally swelling over and distal to the radial styloid. Pathologic findings include inflammation and narrowing of the tendon sheath around the abductor pollicis longus and extensor pollicis brevis. A positive Finkelstein test result is usually seen; pain increases when the thumb is folded across the palm and the fingers are flexed over the thumb as the examiner passively deviates the wrist toward the ulnar side. However, this test also may be positive in patients with osteoarthritis of the first carpometacarpal joint and must be differentiated from this common condition.

TREATMENT

Treatment involves splinting, local corticosteroid injection, such as 0.5 mL of a 40 mg/mL concentration of methylprednisolone acetate (Fig. 242-5), and NSAIDs (Table 26-4) as indicated.[13] Rarely, surgical removal of the obstructive tenosynovium is needed.

Trigger Finger

Trigger finger consists of chondroid metaplasia of the digital flexor pulleys[14,15] and underlying flexor digitorum superficialis and flexor digitorum profundus tendons in the palm. It is extremely common but often unrecognized. Pain in the palm is felt on finger flexion, but in some cases the pain radiates to the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints on the dorsal side, misleading the examiner. The middle and index fingers are most commonly involved, but the ring and little fingers also can be affected. Often a nodule composed of fibrocartilaginous tissue can be palpated in the palm just proximal to the MCP joint on the volar side. The nodule interferes with the normal tendon gliding and can cause a triggering or locking, which may be intermittent and may produce an uncomfortable sensation. Similar involvement can occur at the flexor tendon of the thumb. The most common cause is overuse trauma of the hands from gripping with increased pull on the flexor tendons. Diabetes, the use of aromatase inhibitors,[16] and hypothyroidism predispose to the trigger finger. Trigger finger may be part of inflammatory conditions, such as rheumatoid arthritis, psoriatic arthritis, or apatite crystal deposition disease. It is seen frequently in conjunction with osteoarthritis of the hands.

TREATMENT

Injection of a long-acting steroid, such as 1 mL of a 40 mg/mL concentration of methylprednisolone acetate, into the tendon sheath usually relieves the problem (Fig. 242-6), although surgery on the tendon sheath may be needed in unremitting cases.[17]

Other Finger Abnormalities

Gamekeeper's thumb (skier's thumb) is caused by trauma to the thumb resulting in instability of the first MCP joint. This instability is due to laxity or rupture of the ulnar collateral ligament. It is treated by immobilization, but surgical repair may be necessary.

Avulsion of flexor digitorum profundus (jersey finger) may result from trauma, usually in football, when a player grabs onto a jersey. The distal phalanx,

FIGURE 242-5. Injection of de Quervain tenosynovitis.

FIGURE 242-7. Injection of trochanteric bursitis.

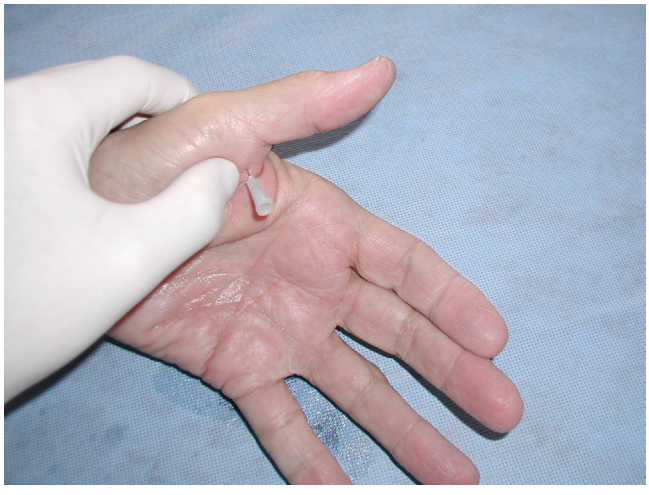

FIGURE 242-6. A trigger thumb occurs commonly. If the patient chooses a steroid injection, the clinician first identifies the two sesamoid bones at the base of the thumb. Then a thin needle is inserted between the two bones that guide the flexor tendon and injects the steroid under low pressure superficial to the tendon.

usually the fourth, is hyperextended while the digitorum profundus is contracting maximally. The avulsion of the tendon results in an inability to flex the distal phalanx of that digit. Surgery is required to correct the problem.

DISORDERS OF THE HIP REGION

Greater Trochanter Pain Syndrome

Although greater trochanter pain syndrome (formerly trochanteric bursitis) is common, it frequently goes undiagnosed. It occurs predominantly in middle-aged to elderly people and somewhat more often in women. The main symptom is aching over the trochanteric area and lateral thigh. Walking, various hip movements, and lying on the involved hip may intensify the pain. Onset may be acute, but more often it is gradual, with symptoms lasting for months. In chronic cases, the patient may fail to locate or describe the pain adequately or the physician may fail to interpret them correctly. Occasionally, the pain has a pseudoradiculopathic quality, radiating down the lateral aspect of the thigh.[18] In a few cases, the pain is so severe that the patient cannot walk and complains of diffuse pain of the entire thigh. The best way to diagnose a greater trochanter pain syndrome is to palpate over the trochanteric area and elicit point tenderness. In addition to specific pain on deep pressure over the back corner of the trochanter, other tender points may be noted throughout the lateral aspect of the thigh muscle. Pain may be worse with external rotation and abduction against resistance. The condition actually arises at the insertions of the gluteus medius and, to a lesser extent, gluteus minimus tendons. Local trauma and degeneration play a role in the pathogenesis, leading to tendinosis and/or tendon tears. Conditions that may contribute to trochanteric bursitis, apparently by adding stress to the area, include osteoarthritis of the lumbar spine or of the hip, leg-length discrepancy, and scoliosis.

TREATMENT

Treatment consists of local injection of depot corticosteroid, such as 1 mL of a 40 mg/mL concentration of methylprednisolone acetate, using a 22-gauge, 3.5-inch needle to ensure that the tender area is reached (Fig. 242-7). NSAIDs (Table 26-4), weight loss, and strengthening and stretching of the gluteus medius muscle and iliotibial band help in management.[19]

Coccydynia

Coccydynia is manifested by pain in the coccyx area when pressure is applied to the area. This most notably occurs on sitting. The patient squirms from buttock to buttock to relieve the pressure and consequent pain and often chooses to sit on a cushion. The symptoms may be chronic and severe. The condition may relate to a fall on the coccyx, dropping to a hard chair when sitting, or some related trauma to the coccyx. However, at times no obvious cause can be detected. Women are much more frequently affected, perhaps because the lordosis that often occurs in women exposes the coccyx to more trauma. The diagnosis is confirmed by finding localized tenderness over the coccyx on palpation. A plain x-ray film can be obtained to exclude a fracture or dislocation of the coccyx.

TREATMENT

Treatment with a local injection of 1 mL of a long-acting corticosteroid, such as a 40 mg/mL concentration of methylprednisolone acetate, and 2 mL of a 2% lidocaine solution is usually very effective. The exact nature of the pathology of coccydynia has not been studied, but it is presumed to be a bone bruise.

Iliopsoas Bursitis

In iliopsoas bursitis, groin and anterior thigh pain are present and worsen on passive hip hyperextension and sometimes on flexion, especially with resistance. Tenderness is palpable over an involved bursa. The patient may hold the hip in flexion and external rotation to eliminate pain and may limp to prevent hyperextension of the hip. The iliopsoas bursa lies behind the iliopsoas muscle, anterior to the hip joint and lateral to the femoral vessels. Independent from the joint at a younger age, the iliopsoas bursa communicates with the hip in approximately 30% of persons by middle age. The diagnosis is more apparent if a cystic mass is seen (approximately 30% of cases); however, other causes of cystic swelling in the femoral area must first be excluded. A bursal mass can cause femoral venous obstruction or femoral nerve compression, and it can progress into the pelvis alongside the iliopsoas muscle. As with most cases of bursitis, acute or recurrent trauma, inflammatory conditions such as rheumatoid arthritis, and a wearing hip prosthesis may lead to iliopsoas bursitis (also called *iliopectineal bursitis*). Iliopsoas tendinosis may overlap with the bursitis or occur independently in a similar clinical picture. The diagnosis is confirmed by ultrasonography, computed tomography, or MRI.

TREATMENT

Iliopsoas bursitis/tendinosis usually responds to conservative treatment, including physical therapy and corticosteroid injections, such as 1 mL of a 40 mg/mL concentration of methylprednisolone acetate. With recurrent involvement, excision of the bursa may be necessary.

Ischial or Ischiogluteal Bursitis

Ischial or ischiogluteal bursitis is caused by trauma or by prolonged sitting on hard surfaces, as evidenced by the name *weaver's bottom*. Pain is often exquisite when sitting or lying down. The hamstring muscles originate from the lateral side of the ischial tuberosity, and the ischiogluteal bursa is superficial to the tuberosity. Because the bursa separates the gluteus maximus from the tuberosity, the pain may radiate down the back of the thigh. Point tenderness over the ischial tuberosity is present.

TREATMENT

Use of cushions, hamstring stretching, and local injection of a corticosteroid, such as 1 mL of a 40 mg/mL concentration of methylprednisolone acetate, are helpful.

DISORDERS OF THE KNEE REGION

Stress Syndromes

Pes anserinus syndrome, formerly called "anserine bursitis" is seen predominantly in overweight, middle-aged to elderly women with large legs and osteoarthritis of the knees. The symptoms are pain and tenderness over the medial aspect of the knee approximately 2 inches below the joint margin, with the pain worsened by climbing stairs. The pes anserinus (Latin for "goose foot") is composed of the conjoined tendons of the sartorius, gracilis, and semitendinosus muscles. The anserine bursa extends between the above tendons and the tibial collateral ligament. Tendinopathy of these tendons or pressure on the tibial collateral ligament by a displaced meniscus may be the predominant causes of the syndrome. The diagnosis is made by eliciting exquisite tenderness over the pes area. Pes anserinus syndrome is often overlooked because it frequently occurs concomitantly with osteoarthritis of the knee, which, when present, is the assumed cause of pain; however, in some cases of dual involvement, pes anserinus syndrome may be the principal source of the pain.

Iliotibial band syndrome manifests by lateral knee pain caused by repetitive stress between the iliotibial band and the lateral femoral condyle. It is an overuse injury and is seen in runners, cyclists, and other athletes performing repetitive knee flexion activities.

TREATMENT

For pes anserinus syndrome, the treatment is rest, stretching of the adductor and quadriceps muscles, and a corticosteroid injection into the tender point, keeping the knee semiflexed. For iliotibial band syndrome, treatment focuses on limiting activities that exacerbate pain, icing, and NSAIDs (Table 26-4), followed by physical therapy. Corticosteroid injections can be used if needed.

Bursitis and Tendinitis

Prepatellar bursitis manifests as a swelling superficial to the kneecap and results from trauma such as frequent kneeling. The prepatellar bursa lies anterior to the lower half of the patella and the upper half of the patellar tendon. The pain is generally slight unless pressure is applied directly over the bursa. Skin erosion, fissures, redness, a puncture wound, or peribursal edema suggest a septic etiology of bursitis. The bursal sac should be aspirated and treated accordingly.

The infrapatellar bursa, which lies between the patellar tendon and the tibia and is homologous to the retrocalcaneal bursa,[20] is also subject to trauma. Rarely, the tibial enthesis of the patellar tendon and the infrapatellar bursa are involved in spondyloarthritis.

Patellar tendinitis (jumper's knee) is seen predominantly in athletes who engage in activities such as repetitive running, jumping, or kicking. Pain and tenderness are present over the patellar tendon.

TREATMENT

Treatment focuses on protecting the knees from irritating trauma. NSAIDs (Table 26-4) are often helpful.

Popliteal Cysts

Popliteal cysts, also known as Baker cysts, are not uncommon, and the clinician should be well aware of the possibility of their dissection or rupture. Popliteal cysts occur by fluid distention of a contiguous bursa behind the medial femoral condyle. Given a connecting bursa, any knee effusion may create a popliteal cyst via a functional unidirectional mechanism. Typically, popliteal cysts become hard in knee extension and soft in flexion.

A cystic swelling behind the knee with mild or no discomfort can be the only initial finding. With further distention of the cyst, however, a greater awareness and discomfort are experienced, particularly on full flexion or extension. The cyst is best seen when the patient is standing and examined from behind. Popliteal cysts reflect the knee conditions that cause effusion and are therefore most commonly seen in rheumatoid arthritis, osteoarthritis, or internal derangements of the knee.

A syndrome of pseudothrombophlebitis may occur as a result of cyst dissection into the calf or actual rupture of the cyst. Findings include diffuse swelling of the calf, pain, and sometimes erythema and edema of the ankle. An incorrect diagnosis of thrombophlebitis (Chapter 68) may lead to anticoagulation and result in compartment syndrome. An ultrasound of the knee confirms both the cyst and the possible dissection or rupture and serves to exclude thrombophlebitis.

TREATMENT

For a cyst related to an inflammatory arthritis, drainage[21] and injection of a depot corticosteroid into the knee joint (and possibly into the cyst itself), such as 1 or 2 mL of a 40 mg/mL concentration of methylprednisolone acetate, resolves the problem. If the cyst results from osteoarthritis or an internal derangement of the knee, an endoscopic enlargement of the connection may become necessary to promote backflow of the excess synovial fluid and prevent a recurrence of the cyst.[22]

Tendon Ruptures

In the knee area, tendon ruptures may occur, and quadriceps tendon rupture is involved approximately 50% of the time; otherwise, patellar tendon rupture occurs. Quadriceps tendon rupture is generally caused by sudden violent contractions of the quadriceps muscle when the knee is flexed. A hemarthrosis of the knee joint may follow. Patients with chronic renal failure, rheumatoid arthritis, hyperparathyroidism, or gout and patients with systemic lupus erythematosus taking steroids have been reported to have spontaneous ruptures of the quadriceps tendon. The patient experiences a sudden sharp pain and cannot extend the leg. The tendon is usually found to be degenerated. Rupture of the patellar tendon has been associated with a specific episode of trauma, repetitive trauma from sporting activities, and systemic diseases. Radiographic studies may show a high-riding patella.

TREATMENT

Surgical repair is often indicated.

Meniscal Tears

Meniscal tears are common causes of knee "locking" and pain. Physical examination may show pain, with or without clicking, when the hip and knee are bent to 90 degrees. MRI is the diagnostic test of choice.

TREATMENT

Physical therapy is often as effective as surgery,[A12,A13] even for patients who complain of knee catching or occasional locking. Isolated tears of the medial and lateral collateral knee ligaments often can be managed without surgery, but tears of the cruciate ligaments typically require surgery.[23]

DISORDERS OF THE ANKLE AND FOOT REGION

Achilles Tendinosis

The distal 2 cm of the Achilles tendon is known as the insertional tendon. The bone attachment or calcaneal enthesis is a complex structure that comprises fibrocartilage laid on the anterior tendon and the opposite calcaneal surface, the space between these cartilaginous layers (known as the retrocalcaneal bursa), and a synovial-lined fat wedge that slides in and out of the bursa with the plantar and dorsal movement of the ankle. This array of structures plus

the underlying trabecular bone is known as the Achilles entheseal organ and is a prime site of involvement in spondyloarthritis (Chapter 244). Calcium pyrophosphate dihydrate crystals and homogentisic acid in ochronosis may also involve the distal tendon. Rheumatoid arthritis and gout may also affect the bursa.

To identify retrocalcaneal bursitis, the clinician places the thumb and index fingers of one hand at either side of the insertional tendon. Then, the other index presses repeatedly over the tendon, perceiving fluid fluctuation with the exploring fingers. Superficial to the tendon insertion, improperly fitting shoes with a stiff heel may irritate the subcutaneous retro Achilles bursa and cause severe local pain. The noninsertional Achilles tendon extends from 2 to 6 cm proximal to the calcaneal insertion. Tendinopathy, tendon ruptures, gout tophi, and rheumatoid nodules tend to appear in this segment. In tendinopathy, the involved tendon feels irregularly thickened and is tender to compression. Crepitus on motion and pain on dorsiflexion may be present.

TREATMENT

Management includes NSAIDs (Table 26-4), rest, shoe corrections, heel lift, gentle stretching, and sometimes a splint with slight plantar flexion. Corticosteroid injections by an expert are also beneficial.[A14] The treatment should be followed by calf-muscle exercise therapy.[A15] Platelet-rich plasma injection is of no benefit.[A16]

Achilles Tendon Rupture

The Achilles tendon is vulnerable to rupture, which occurs with a sudden onset of pain during forced dorsiflexion. An audible snap may be heard, followed by difficulty in walking and standing on toes. Swelling and edema over the area usually develop. Diagnosis can be made with the Thompson test, in which the patient kneels on a chair with the feet extending over the edge and the examiner squeezes the calf and pushes toward the knee. Normally this produces plantar flexion, but in a ruptured tendon, no plantar flexion occurs. An intact plantaris muscle may result in a false-negative Thompson test. Achilles tendon rupture usually occurs during athletic events or with trauma from jumps or falls. The tendon is more prone to tear in older people, people with preexisting Achilles tendon disease, and in persons taking corticosteroids or fluoroquinolone antibiotics.[24]

TREATMENT

Orthopedic consultation should be obtained, and immobilization or surgery may be selected, depending on the situation,[25] with either providing equivalent results.[A17] If immobilization is chosen, early weight bearing with a functional brace is equivalent to a plaster cast.[A18]

Ankle Sprain

For acute, severe ankle sprain, a below-knee cast or Aircast produces a faster recovery than a tubular compression bandage, but there is no difference in outcomes at 9 months.

Plantar Fasciitis

Plantar fasciitis, which is seen primarily in persons between 40 and 60 years of age, is characterized by pain in the plantar area of the heel. The onset may be gradual, or it may occur with trauma or overuse from some activity, such as athletics, prolonged walking, using improper shoes, or striking the heel with some force. Plantar fasciitis may be idiopathic; it also is likely to be present in younger patients with spondyloarthritis (Chapter 244). The pain characteristically occurs in the morning on arising and is most severe for the first few steps. After an initial improvement, the pain may worsen later in the day, especially after prolonged standing or walking. The pain is burning, aching, and occasionally lancinating. Palpation typically reveals tenderness anteromedially on the medial calcaneal tubercle at the origin of the plantar fascia.

TREATMENT

Treatment includes relative rest with a reduction in stressful activities, NSAIDs (Table 26-4), use of a contoured full-length insole,[26] and stretching of the heel cord and plantar fascia. A local corticosteroid injection, such as 0.5 to 1 mL of a 40 mg/mL concentration of methylprednisolone acetate using a 25-gauge needle, is often of help. Avoid repeating these injections, which carry the risk of fat atrophy and chronic pressure pain.

Posterior Tibial Tendinitis

In posterior tibial tendinitis, pain and tenderness occur just posterior to the medial malleolus; it can be caused by trauma, excessive pronation, rheumatoid arthritis, or spondyloarthropathy. Extension and flexion may be normal, but pain is present on resisted inversion or passive eversion. The discomfort is usually worse after athletic activity, and swelling and localized tenderness may be present.

TREATMENT

Treatment usually includes rest, NSAIDs (Table 26-4), and possibly a local injection of corticosteroid with 0.5 mL of a 40 mg/mL concentration of methylprednisolone acetate. Immobilization with a splint is sometimes needed.

Posterior Tibialis Tendon Rupture

Posterior tibialis tendon rupture, which is not commonly recognized, is a cause of progressive flat foot. It can result from trauma, chronic tendon degeneration, or rheumatoid arthritis. An insidious onset of pain and tenderness may be noted along the course of the tendon just distal to the medial malleolus, along with swelling medial to the hind foot. The unilateral deformity of hind foot valgus and forefoot abduction is an important finding. The forefoot abduction can be best seen from behind; more toes are seen from this position than would be seen normally. The result of the single heel rise test is positive when the patient is unable to rise onto the ball of the affected foot while the contralateral foot is off the floor.

TREATMENT

Treatment usually includes rest, NSAIDs (Table 26-4), and possibly an orthosis. Surgical repair of the tendon is sometimes indicated.

Turf Toe

Turf toe is an injury of the big toe originally described during play on artificial turf. It results from hyperextension of the first metatarsophalangeal (MTP) joint when a fixed, dorsiflexed foot is forced into the ground. The plantar capsular ligament may be sprained or torn.

TREATMENT

Treatment is conservative, with rest, ice, elevation, and NSAIDs (see Table 26-4) as needed.

Morton Neuroma

Morton neuroma (Fig. 242-8) is a prominent cause of forefoot pain and paresthesia in individuals who wear shoes that are too narrow for the width of their metatarsal arches and high heels that drive the forefeet into those limited spaces. The compressed nerve, surrounded by reactive fibrous tissue, supplies the opposing halves of two contiguous toes, generally the third and the fourth. Multiple nerves may be involved.[27] Typically, symptoms do not appear wearing sandals.

TREATMENT

Treatment requires a change in footwear. Symptoms may be temporarily relieved by steroid injection, such as 1 mL of a 40 mg/mL concentration of methylprednisolone acetate. Neurectomy permanently relieves the local symptoms.[A19]

Stress Fracture

Stress fracture is also known as march fracture or fatigue fracture because it was first associated with spontaneous fracture after long marches in army recruits. Pain, swelling, tenderness, and occasionally erythema develop over the metatarsal area, usually without any clear history of trauma. On questioning, however, the episode of spontaneous pain related to onset of the fracture can be identified in some cases. The neck of the second metatarsal bone is most frequently involved, but the third metatarsal is also a site of fracture and less commonly seen in the fourth and fifth metatarsals. Aside from prolonged

FIGURE 242-8. Patient with Morton neuromas in both feet.

marching, other athletic events with overactivity, including jogging, are common causes. Stress fractures may be seen in patients with rheumatoid arthritis, in postmenopausal women, and in older people. The difficulty in diagnosing stress fractures is that the initial x-ray films usually show no abnormalities or, at most, only a faint fracture line. A repeat radiographic examination several weeks later shows healing with callus formation. Bone scans aid the early diagnosis of stress fractures by showing an increase in uptake over the fracture site.

TREATMENT

Usually these fractures heal spontaneously, and rest and strapping of the foot are helpful. Occasionally, a cast is needed.

243 RHEUMATOID ARTHRITIS

IAIN B. MCINNES

DEFINITION

Rheumatoid arthritis is a chronic systemic inflammatory disease of unknown etiology that primarily targets synovial tissues. The primary target of rheumatoid arthritis is the joint, but systemic inflammation is thought to be responsible for a variety of coexistent comorbid conditions, including cardiovascular disease, osteoporosis, cognitive dysfunction, psychiatric disease, and cancer.

EPIDEMIOLOGY

Rheumatoid arthritis is a global disease with a variable geographic prevalence of 0.5 to 1% of adults. The prevalence is about three times greater in women before menopause than in men. Rheumatoid arthritis can occur at any age. Overall, the annualized incidence of rheumatoid arthritis is approximately 40 per 100,000 for women and about half that for men. Because rheumatoid arthritis is a lifelong disease and its incidence increases or is stable with age, the prevalence of rheumatoid arthritis increases with each decade. The incidence of rheumatoid arthritis may be decreasing, perhaps reflecting reductions in smoking. Geographic variations in prevalence and phenotype can be remarkable. Most notably, in rural Nigeria, cohorts in which no individuals are affected with rheumatoid arthritis have been described, though case ascertainment bias needs to be excluded. In contrast, a prevalence of 5% has been found in some studies of Chippewa, Yakima, and Inuit Native Americans. Such extreme phenotypes are poorly understood but likely reflect the impact of genetics, the gastrointestinal or respiratory microbiome, or other environmental influences.

PATHOBIOLOGY

Genetics

A combination of candidate association, twin, and genome-wide association studies (GWAS) has established a strong genetic component to the risk for developing rheumatoid arthritis and the severity of the disease.[1] Twin studies reveal a concordance rate of approximately 12 to 15% for monozygotic twins and 2 to 5% for dizygotic twins. Heritability is reported to be around 60%, with lower values for patients who are seronegative for autoantibodies.[2]

GWAS in European, North American, and recently Asian populations, combined with subsequent meta-genome analyses, demonstrate that rheumatoid arthritis is a polygenic disorder. The majority of more than 100 thus far identified informative single nucleotide polymorphisms (SNPs) implicate immune genes, indicative of a primary immunologic etiology. Around 40% of genetic risk accrues in the HLA region. Certain HLA-DR alleles (e.g., DRB*0401, DRB*0404, DRB*0101, DRB*1402) associate with an increased risk for

marching, other athletic events with overactivity, including jogging, are common causes. Stress fractures may be seen in patients with rheumatoid arthritis, in postmenopausal women, and in older people. The difficulty in diagnosing stress fractures is that the initial x-ray films usually show no abnormalities or, at most, only a faint fracture line. A repeat radiographic examination several weeks later shows healing with callus formation. Bone scans aid the early diagnosis of stress fractures by showing an increase in uptake over the fracture site.

TREATMENT

Usually these fractures heal spontaneously, and rest and strapping of the foot are helpful. Occasionally, a cast is needed.

243 RHEUMATOID ARTHRITIS

IAIN B. MCINNES

DEFINITION

Rheumatoid arthritis is a chronic systemic inflammatory disease of unknown etiology that primarily targets synovial tissues. The primary target of rheumatoid arthritis is the joint, but systemic inflammation is thought to be responsible for a variety of coexistent comorbid conditions, including cardiovascular disease, osteoporosis, cognitive dysfunction, psychiatric disease, and cancer.

EPIDEMIOLOGY

Rheumatoid arthritis is a global disease with a variable geographic prevalence of 0.5 to 1% of adults. The prevalence is about three times greater in women before menopause than in men. Rheumatoid arthritis can occur at any age. Overall, the annualized incidence of rheumatoid arthritis is approximately 40 per 100,000 for women and about half that for men. Because rheumatoid arthritis is a lifelong disease and its incidence increases or is stable with age, the prevalence of rheumatoid arthritis increases with each decade. The incidence of rheumatoid arthritis may be decreasing, perhaps reflecting reductions in smoking. Geographic variations in prevalence and phenotype can be remarkable. Most notably, in rural Nigeria, cohorts in which no individuals are affected with rheumatoid arthritis have been described, though case ascertainment bias needs to be excluded. In contrast, a prevalence of 5% has been found in some studies of Chippewa, Yakima, and Inuit Native Americans. Such extreme phenotypes are poorly understood but likely reflect the impact of genetics, the gastrointestinal or respiratory microbiome, or other environmental influences.

PATHOBIOLOGY

Genetics

A combination of candidate association, twin, and genome-wide association studies (GWAS) has established a strong genetic component to the risk for developing rheumatoid arthritis and the severity of the disease.[1] Twin studies reveal a concordance rate of approximately 12 to 15% for monozygotic twins and 2 to 5% for dizygotic twins. Heritability is reported to be around 60%, with lower values for patients who are seronegative for autoantibodies.[2]

GWAS in European, North American, and recently Asian populations, combined with subsequent meta-genome analyses, demonstrate that rheumatoid arthritis is a polygenic disorder. The majority of more than 100 thus far identified informative single nucleotide polymorphisms (SNPs) implicate immune genes, indicative of a primary immunologic etiology. Around 40% of genetic risk accrues in the HLA region. Certain HLA-DR alleles (e.g., DRB*0401, DRB*0404, DRB*0101, DRB*1402) associate with an increased risk for

ABSTRACT

Rheumatoid arthritis is a chronic inflammatory disease affecting primarily the joints but is associated with substantial comorbidities that include cardiovascular, psychologic, oncologic, and systemic bone disease. The underlying pathogenesis of rheumatoid arthritis is incompletely understood but comprises an early breach of tolerance to a range of post-translational modifications, typically citrullination or acetylation of "self'-proteins," thereby leading to the elaboration of autoantibodies, cytokines, and chemokines, as well as dysregulated metabolism up to 10 years before clinically detectable disease. The primary target tissue is the synovium, which contains a range of activated leukocytes and stromal cells that, under the influence of inflammatory cytokines, drive local cartilage and bone destruction. Therapeutics include the sequential administration of disease modifying antirheumatic drugs (DMARDs), initially including methotrexate and escalating thereafter to the use of other DMARDS, biologic agents (including TNF and IL-6 receptor inhibitors), rituximab, abatacept, and Janus kinase inhibitors. Parallel use of NSAIDs and judicious use of corticosteroids are also common practice, though use of both should be minimized. Therapeutics should be adjusted based on formally assessed, intercurrent levels of disease activity, to seek the lowest level of disease activity or remission, whichever is more appropriate for a given patient. Long-term outcomes have improved remarkably, but a small group of patients has difficult to treat disease.

developing rheumatoid arthritis and thereafter progressing to more severe disease. Hypervariable regions on DR molecules are particularly important for antigen recognition by binding to antigenic peptides and presenting them to the T-cell receptor (TCR). The amino acid sequence of disease associated DRβ1 chains share a common structural motif, called the *shared epitope* (E-Table 243-1).

Peptides derived from post-translationally modified proteins (e.g., via citrullination, acetylation, carbamylation) may bind with altered avidity to the shared epitope, thereby providing a potential mechanism whereby this genetic factor can mediate the risk of disease at the molecular level. Thus, altered binding of such peptides to the HLA molecule (expressed on dendritic cells or B cells) may alter the dynamics of HLA-TCR interactions and thereby confer loss of self-tolerance upon (self-reactive) T cells inappropriately activated by this abnormal receptor engagement.

Many other immune related genes have been implicated and add considerable depth to the understanding of pathogenetic pathways. Although individual SNPs usually exhibit modest risk contribution (odds ratios ≈1.05 to 1.2-fold), they nevertheless could confer significant functional impact. Risk genes can be usefully defined on the basis of their contribution to functional immune system compartments. Adaptive immunity-associated SNPs include a functional polymorphism in protein tyrosine phosphatase nonreceptor 22 (*PTPN22*), a polymorphism that has been reproducibly associated with rheumatoid arthritis and a number of other autoimmune diseases, including type 1 diabetes, systemic lupus erythematosus, Graves disease, and Hashimoto thyroiditis. The costimulation receptors, CTLA, CD28, CD40, and signal protein kinase TYK2 have similar disease associations. An association with peptidyl arginase deiminase also has been recognized. Because this enzyme converts arginine to citrulline, it may confer a genetically predisposed risk via increased generation of a major rheumatoid arthritis autoantigen. Pathways that regulate innate immune pathways are also identified (e.g., *TRAF1-C5, STAT4*, TNF-AIP3, IRAK1) together with pathways concerned with cell migration *(ELMO1)* and fetal development *(LBH)*. Several SNPs identify cytokine or cytokine receptor coding loci, including TNF and IL-6R.

Finally, there is increased interest in the role of epigenetics in disease risk and especially propagation. Altered DNA methylation, histone modification (e.g., via acetylation), and microRNA expression patterns associate with increased or perpetuation of inflammation. These patterns have been best defined in fibroblast-like synoviocytes (e.g., differential methylation and thus gene expression has been found particularly for pathways related to cell growth and differentiation). The presence of differentially expressed microRNAs has also attracted attention in myeloid lineage cells, T cells, and fibroblast-like synoviocytes. For example, dysregulation of miR146 and miR155 promotes cytokine and inflammatory pathways in macrophages.

Etiology

Increasing evidence supports a substantial role for environmental factors including smoking, other pulmonary exposures (e.g., silica), obesity, vitamin D deficiency, and lower educational attainment as risk factors for rheumatoid arthritis. Low levels of alcohol intake may be protective (E-Fig. 243-1). Smoking in particular has long been associated with a significantly increased risk for developing rheumatoid arthritis, but only for anti-citrullinated peptide antibody (ACPA)-positive disease, especially in patients who have the shared epitope. Induction of epigenetic changes by smoking provides the most likely explanation for this etiologic link. Infectious triggers are also implicated, such as *Mycobacteria, Streptococcus, Mycoplasma, Escherichia coli, Helicobacter pylori*, and viruses (rubella, Epstein-Barr, parvovirus). The mechanisms whereby infections drive disease are poorly understood, but rheumatic fever (Chapter 269), reactive arthritis (Chapter 244), and Lyme arthritis (Chapter 296) are prime examples. Reactive arthritis in particular may occur following one of a myriad of different but specific infectious triggers presented to a specific location in the body (e.g., the gastrointestinal or genitourinary tract) on a predisposed genetic background, in most cases human leukocyte antigen (HLA)-B27. In this syndrome, age and gender and hence the maturity of the immune system may be critical in the development of clinical disease, which occurs primarily between the ages of 15 and 40 years in males. Many other examples exist in animal models of arthritis, including arthritis induced by mycobacteria and streptococci. Studies of the gastrointestinal and oral microbiome (the latter particularly in periodontal disease) have identified dysbiosis associated with early rheumatoid arthritis. Specific microbes (e.g., *Porphyromonas gingivalis*, *Prevotella copri, Aggregatibacter actinomycetemcomitans*) have been implicated. Whether these associations represent molecular mimicry, altered immune homeostasis (the gastrointestinal tract is a vital area for maintenance of peripheral immunologic tolerance), or direct stimulation of immune function (e.g., via enhanced citrullination) remains under investigation.

The use of oral contraceptives has been associated with a decrease in the incidence of rheumatoid arthritis. Because the effect appears to be strongest for oral contraceptives that have high estrogen content, it is postulated that estrogen is responsible for this protective effect.

Pathogenesis and Tissue Pathology

The overarching pathogenesis of rheumatoid arthritis remains unknown. The earliest signs of inflammation often occur in the lung: abnormal high-resolution CT scans of pre-rheumatoid arthritis patients have been reported. Pulmonary mucosal citrullination is increased, perhaps reflecting smoking or other pulmonary irritants. Increased local inflammation supports initial B-cell and then T-cell activation, with consequent "breach of tolerance" to post-translationally modified self proteins. Similar events in the oral mucosa, in periodontal disease, or conceivably in the gastrointestinal tract may also contribute in some patient subgroups. The physico-chemical properties of these self-protein derived peptides that confer increased immune activation presumably arise within the genetic architecture described above and especially the structure of the shared epitope. A prearticular clinical phase (pre-rheumatoid arthritis) ensues and may persist for up to several years, during which rheumatoid factor and autoantibodies against post-translationally modified proteins (AMPA), particularly anti-citrullinated peptide antibodies (ACPA), rise in titer and with increasingly broad specificity (epitope spreading). ACPAs, for example, can recognize citrullinated residues on a variety of self-proteins (e.g., type II collagen, vimentin, α-enolase, fibronectin, fibrinogen, and histones). The abnormalities thus appear to represent a broad failure to regulate immune homeostasis, rather than one individual (auto)antigen driving disease overall. One autoantigen may, however, serve as a trigger. In parallel, elevated levels of serum cytokines and chemokines are detected, indicative of generalized increased levels of systemic inflammation, along with lipid dysmetabolism. Biopsies of synovial tissue during this pre-rheumatoid arthritis phase are essentially normal, consistent with the systemic nature of this disease phase.

Thereafter, a transitional event heralds the onset of clinically detectable arthritis. Systemic disease becomes localized to the joint.[3] ACPA specificities are broadest (they expand before the onset of rheumatoid arthritis), and cytokine concentrations are highest immediately before the onset of disease (imminent rheumatoid arthritis). Altered ACPA glycosylation also precedes clinical disease. Early changes in synovial vascularization, deposition of immune complexes, altered neurologic supply, local infection, and microtrauma have all been postulated as articular localizing mechanisms.

Established rheumatoid arthritis is associated with the development of a dense synovial cellular infiltrate that has some degree of organization (E-Fig. 243-2). A lining layer of 4 to 8 cells in depth includes macrophages and fibroblast-like synoviocytes. The interstitial area contains large numbers of T cells, B cells, plasma cells, mast cells, and fibroblast-like synoviocytes. In some patients, lymphocytic aggregates form (ectopic germinal centers), likely serve as a source of autoantibody production, and confer a poorer clinical prognosis. Biopsy studies have identified discrete synovial appearances across patient subgroups; myeloid, lymphocytic, and fibroblastic pathotypes have been described at the transcriptional and histologic level. These pathotypes may represent clinically discrete endotypes that, in the future, could define useful biomarkers to determine optimal choices of immune targeted therapies.[4]

The synovial T-cell response is primarily of T_H1 and T_H17 type. T cells are activated via antigen presented in a CD28/CD80/86 dependent manner by macrophages, B cells, fibroblast-like synoviocytes, the local cytokine milieu (e.g., IL-7, IL-15, TNF, IL-6), or cognate cellular activation through cell contact with macrophages. The T cells secrete cytokines (e.g., IL-17 and GM-CSF) that drive further synovial proliferation. The predominant source of synovial cytokines is, however, macrophages, mast cells, and fibroblast-like synoviocytes. Macrophage-derived cytokines, particularly interleukin-1 (IL-1), IL-6, and tumor necrosis factor-α (TNF-α), play central roles in this ongoing inflammatory process. TNF and IL-6 in particular appear to have hierarchical

functional dominance, as reflected in successful therapeutic targeting (e.g., TNF inhibitors, tocilizumab, and JAK inhibitors).

The humoral immune system also plays a role, as reflected in the success of rituximab therapy. Rheumatoid factor and the presence of ACPAs correlate with more severe disease, including erosions of bone, and with the presence of extra-articular features. Rheumatoid factor, which is an antibody that recognizes the Fc portion of immunoglobulin G as its antigen, and ACPAs likely have a pathologic role. Via immune complex formation or perhaps functioning in isolation, these factors increase complement activation, promote macrophage activation to release lysosomal enzymes, kinins, prostanoids, and oxygen/nitrogen free radicals via Fc receptor (FcR) binding and may activate osteoclasts. ACPAs also activate macrophages via TLR/FcR cross-talk mediated via citrullinated fibronectin.

Articular damage is driven primarily by fibroblast-like synoviocytes and osteoclasts. Fibroblast-like synoviocytes are partially transformed cells that have a distinct epigenetic profile and that exhibit anchorage independence, loss of contact inhibition, low-grade proliferation, and TLR expression, thereby rendering them immunologically competent to sense tissue damage. Single cell sequencing studies have shown functionally distinct subsets of fibroblast-like synoviocytes, some with bone erosive propensity and others with a more inflammatory phenotype.[5] Fibroblast-like synoviocyte subsets release prostanoids, cytokines, chemokines, and matrix metalloproteinases (MMPs) such as MMP1, MMP3, and MMP13, in disproportion to the release of tissue inhibitors of MMPs (TIMPs). In consequence, fibroblast-like synoviocytes promote cartilage damage; this local tissue damage area is known as the *cartilage-pannus junction*. Macrophages and mast cells are also likely to contribute to this local process. Subsets of macrophages can be defined by single cell sequencing that clearly differentiates synovitis in active disease as compared with remission.[6] Bone damage requires cells with capacity to acidify the local milieu—osteoclast maturation and activation is a localized feature of rheumatoid arthritis synovium, arising as a consequence of RANKL, IL-1, TNF, and IL-17 activity. Thus activated osteoclasts localize in periarticular bone and in the adjacent bone marrow, thereby leading to the characteristic erosions detected on plain radiography. The inflammatory process underlying erosion is detected as "bone edema" on MRI. Synovitis thus results in the destruction of cartilage in marginal bone and in the stretching or rupture of the joint capsule or tendons and ligaments. Damage is directly related to disability.

Finally, generalized inflammation promotes systemic comorbidities. Circulating cytokines and immune complexes are proposed to activate endothelium and accelerate atherosclerosis, may provoke systemic osteoporosis, and can drive cognitive impairment, fatigue, and frank psychiatric presentations (e.g., depression). Inhibition of such processes should reduce comorbidities in the clinic.

CLINICAL MANIFESTATIONS

Although the presentation is variable, most patients with rheumatoid arthritis exhibit insidious onset of pain, stiffness, or swelling in multiple small joints over the course of weeks to months. Systemic features such as fatigue, low-grade fevers, and weight loss also may be present. Less commonly, the onset can be fulminant, occurring almost overnight, or patients may exhibit persistent monoarthritis or oligoarthritis for prolonged periods before manifesting the more typical pattern of joint involvement. Rarely, particularly men develop extra-articular features of rheumatoid arthritis, especially lung disease, before the joint problems appear. Periodic flares of disease are common and may be associated with an increase in circulating pre-inflammatory mesenchymal cells.[7,8]

Morning stiffness is a hallmark of inflammatory arthritis and is a prominent feature of rheumatoid arthritis. Patients are characteristically at their worst in the morning or after prolonged periods of rest. This stiffness in and around joints often persists for hours, and quantifying it is one way to measure impact of an intervention.

Articular Manifestations

Rheumatoid arthritis can affect any of the synovial (diarthrodial) joints (Fig. 243-1). Most commonly, clinically apparent disease starts in the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and metatarsophalangeal (MTP) joints, followed by the wrists, knees, elbows, ankles, hips, and shoulders, in roughly that order. Early treatment limits the extent of joints involved. Less commonly, and usually later, rheumatoid arthritis may involve the temporomandibular, cricoarytenoid, and sternoclavicular joints. Rheumatoid arthritis may involve the upper part of the cervical spine, particularly the C1-C2 articulation (Fig. 243-2), but, unlike the spondyloarthropathies (Chapter 244), it rarely involves the remainder of the spine. Patients are also at an increased risk for osteoporosis (Chapter 225), and this risk should be considered and dealt with early in both women and men.

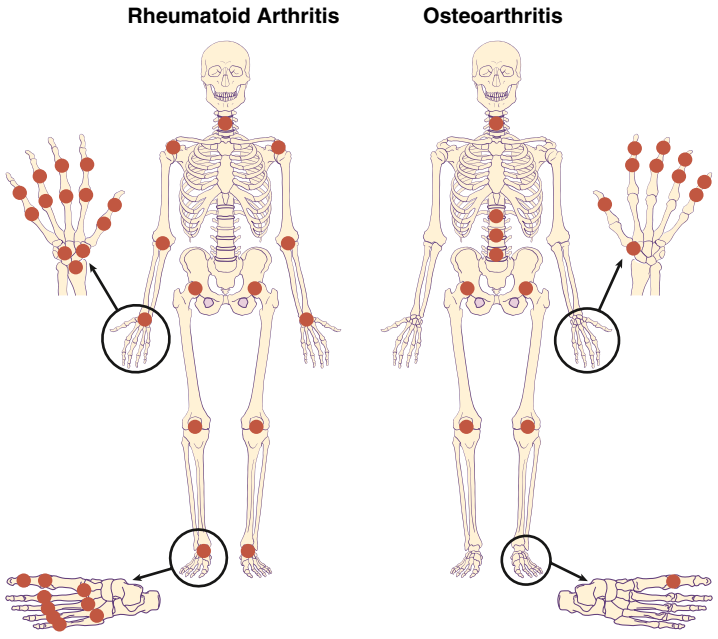

FIGURE 243-1. Distribution of involved joints in the two most common forms of arthritis: rheumatoid arthritis and osteoarthritis. ***Black circles*** **are shown over the involved joint areas.**

Hands

A significant proportion of the disability caused by rheumatoid arthritis is due to damage and dysfunction of the hands. Typically disease starts with swelling of the PIPs and MCPs. The distal interphalangeal (DIP) joints are almost never involved; significant involvement of the DIP joints should suggest the possibility of a different diagnosis (e.g., osteoarthritis or psoriatic arthritis). Manifestations that can be seen late in the disease but are rarely seen in treated patients include the classic ulnar deviation of the MCP joints (Fig. 243-3), and swan-neck deformities (hyperextension of the PIP joints). Boutonnière (or buttonhole) deformities also occur as a result of hyperflexion of the PIP joints. If the clinical disease remains active, hand function deteriorates. Sudden loss of function of individual fingers may occur as a result of tendon rupture.

Feet

Feet, particularly the MTP joints, are involved early in most patients and are often an initial site of radiographic erosion. Subluxation of the toes is common and leads to the dual problem of breakdown of the skin and ulcers on the top of the toes and malalignment of the MTP heads. Painful ambulation is caused by dislocation of the cushioning pads that usually protect the heads of the MTP joints.

Wrists

The wrist joints are involved in most patients with rheumatoid arthritis. Radial deviation is the rule, and patients with severe involvement may progress to volar subluxation. Even early in the course of the disease, synovial proliferation in and around the wrists may compress the median nerve, thereby causing carpal tunnel syndrome (Fig. 243-4). Later, this synovial proliferation may invade tendons and lead to rupture, most commonly of extensor tendons.

Large Joints

Involvement of knees, ankles, elbows, hips, and shoulders is common. Characteristically, the whole joint surface is involved in a symmetrical fashion. Rheumatoid arthritis is symmetrical, not only from one side of the body to the other but also within the individual joint. In the knee (Fig. 243-5A), both the medial and lateral compartments may be narrowed. In contrast, in

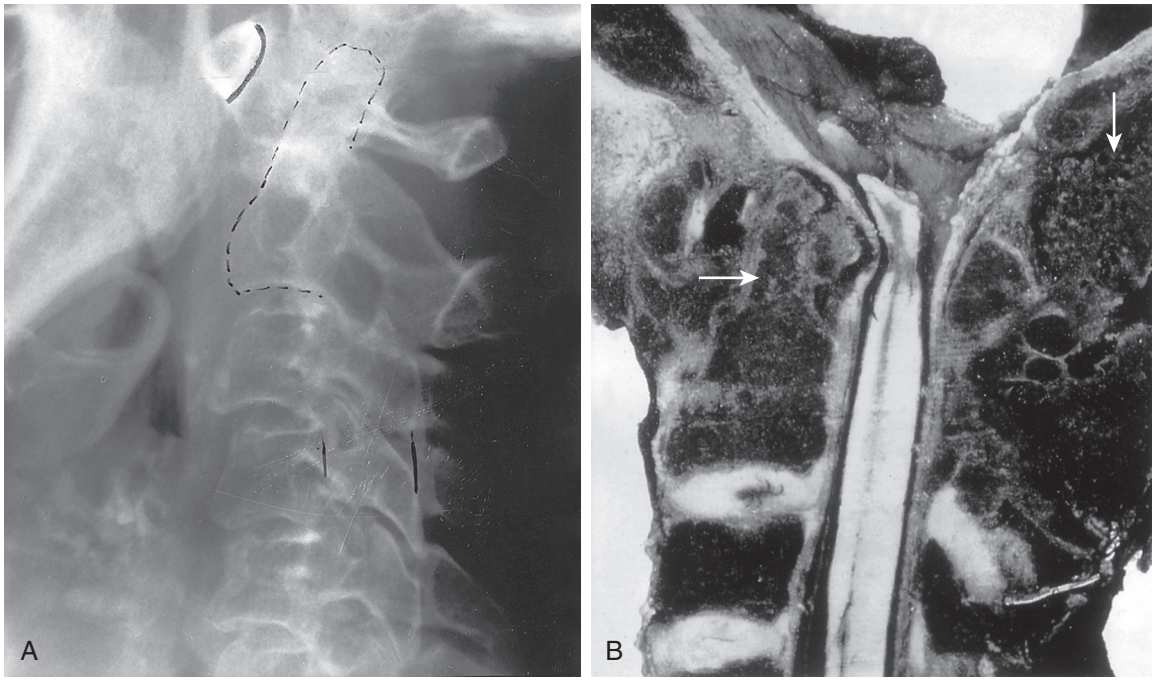

FIGURE 243-2. Subluxation of the cervical spine in patients with rheumatoid arthritis. A, In a lateral radiograph of the cervical spine, the body of C2 and its odontoid process are outlined by the *broken lines* and the posterior aspect of the anterior segment of C1 is indicated by a *solid line*. Normally, a space of only 2 to 3 mm separates C1 from C2. The space between C1 and the odontoid of C2 is markedly increased, indicative of subluxation of C1 and C2. **B,** Lateral view of a pathologic specimen from a patient who died of C1-C2 subluxation. The *horizontal arrow* shows the odontoid process that subluxed posteriorly, severely compressing and almost severing the cord. The *vertical arrow* shows a bone graft that had been put in place posteriorly in an attempt to prevent subluxation. Below the *arrow*, a nonhealing area is present through the bone graft, and inferior to that a wire fixation suture is still in place.

patients with osteoarthritis (Fig. 243-5B), only one compartment of the knee may be involved.

Synovial cysts, which may occur around any of the joints (large or small), occasionally manifest as soft, fluctuant masses that present diagnostic challenges. When the knee produces excess synovial fluid, it may accumulate in the popliteal fossa (popliteal or Baker cyst) (E-Fig. 243-3). These cysts can compress the popliteal nerve, artery, or veins. Baker cysts may dissect into the tissues of the calf (usually posteriorly), or they may rupture. Dissection may produce only minor symptoms, such as a feeling of fullness; rupture of the cyst with extravasation of its inflammatory content produces significant pain and swelling and may be confused with thrombophlebitis, the so-called pseudothrombophlebitis syndrome (Chapter 68).

Neck

Although most of the axial skeleton is spared in rheumatoid arthritis, the cervical spine is commonly involved, particularly the C1-C2 articulation. Bony erosions and ligament damage can occur in this area and may lead to subluxation (see Fig. 243-2). Most often, subluxation at C1-C2 is minor and without accompanying symptoms; patients and caregivers need only be cautious and avoid actively forcing the neck into positions of flexion. Occasionally, subluxation at C1-C2 is severe and leads to compromise of the cervical cord with neurologic symptoms and even death.

Other Joints

Other joints that may be involved include the temporomandibular, cricoarytenoid, and sternoclavicular joints. The cricoarytenoid joint is responsible for abduction and adduction of the vocal cords, and involvement of this joint may lead to a feeling of fullness in the throat, to hoarseness, and, rarely when the cords are essentially fused in a closed position, acute respiratory distress with or without stridor.

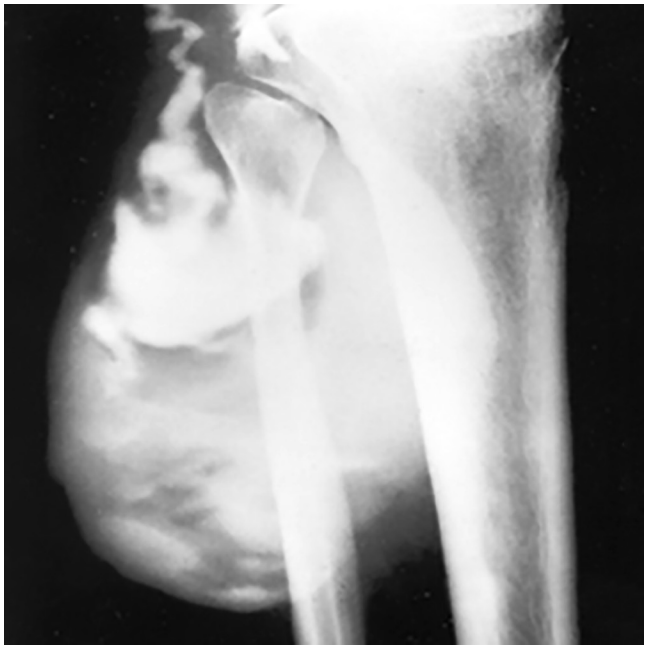
Extra-Articular Manifestations

Systemic features of rheumatoid arthritis such as fatigue, weight loss, and low-grade fevers occur frequently. All the other extra-articular features are more common in patients who are positive for rheumatoid factor, ACPA antibodies, or both (Table 243-1).

FIGURE 243-3. Severe advanced rheumatoid arthritis of the hands. There is massive tendon swelling over the dorsal surface of both wrists, severe muscle wasting, ulnar deviation of the metacarpophalangeal joints, and swan-neck deformity of the fingers. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

Skin

Subcutaneous nodules are seen in approximately 20% of patients with rheumatoid arthritis, almost exclusively in patients who are rheumatoid factor- or ACPA-positive. Seronegative patients with nodules should be carefully scrutinized for a different diagnosis, such as chronic tophaceous gout (Chapter 252). Nodules may occur almost anywhere (e.g., lungs, heart, eye) but most commonly develop subcutaneously on extensor surfaces (particularly the forearms) (Fig. 243-6), over joints, or over pressure points. Rheumatoid nodules are firm on examination, usually are not tender, have a characteristic histologic picture, and are thought to be initiated by small vessel vasculitis. A syndrome



E-FIGURE 243-3. Arthrogram with a radiocontrast agent injected into the knee. The dye flows into the popliteal space and through a narrow channel into a large synovial cyst (Baker cyst) that has dissected into the soft tissue of the calf. Arthrograms are no longer used in routine diagnostics, but this dramatic image beautifully illustrates the phenomenon.

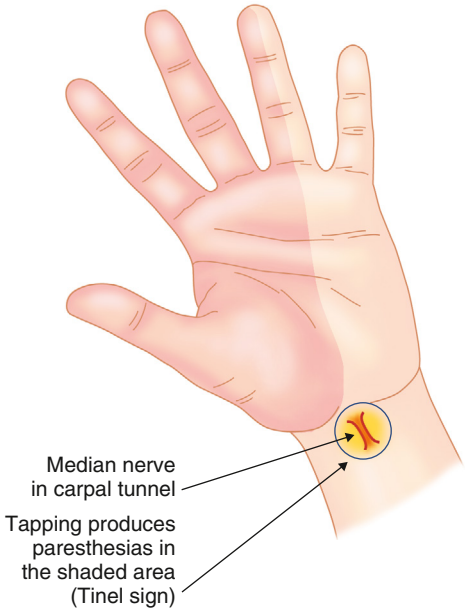


FIGURE 243-4. Carpal tunnel syndrome. Distribution of pain and/or paresthesias *(shaded area)* when the median nerve is compressed by swelling in the wrist (carpal tunnel).

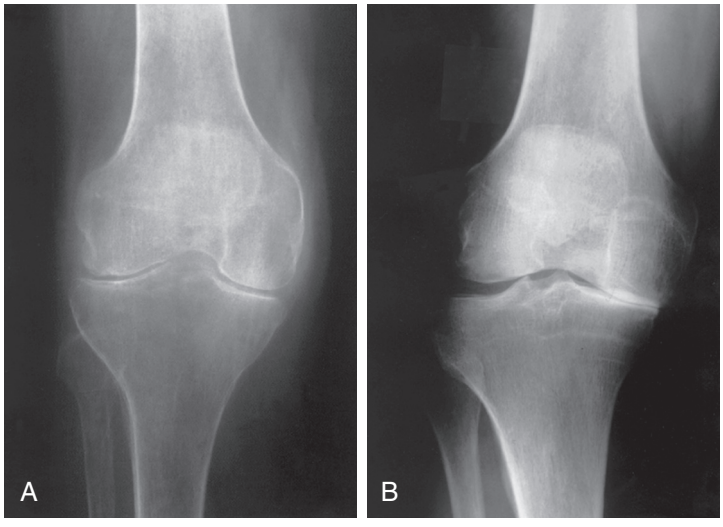

FIGURE 243-5. Radiographs of the knees in the two most common forms of arthritis: rheumatoid arthritis and osteoarthritis. A, Severe involvement in rheumatoid arthritis, with almost complete symmetrical loss of joint space in both the medial and the lateral compartments, but with little subchondral sclerosis or osteophyte formation. **B,** Typical osteoarthritis, with severe, near-total loss of joint space of one compartment and a normal or actually increased joint space of the other compartment. Note also the significant subchondral sclerosis in the involved area, typical of osteoarthritis.

of increased nodulosis, despite good control of the joint disease, has been described with methotrexate therapy (Fig. 243-7).

Small vessel vasculitis, manifested as digital infarcts or leukocytoclastic vasculitis, may occur in rheumatoid arthritis (Fig. 243-8) Vasculitis of small and medium arteries may be indistinguishable from polyarteritis nodosa. Pyoderma gangrenosum also occurs with increased frequency in association with rheumatoid arthritis.

Cardiovascular Involvement

Cardiac involvement directly related to rheumatoid arthritis is uncommon, but patients with rheumatoid arthritis have significantly increased morbidity and mortality from coronary artery disease and heart failure. Chronic inflammation superimposed on conventional risk factors (e.g., smoking, obesity) appears to be the major cause. Some of the medications used to treat rheumatoid arthritis such as glucocorticoids and a sedentary lifestyle may be additional risk factors for the development of coronary artery disease.

TABLE 243-1 EXTRA-ARTICULAR MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Skin	Nodules, fragility, vasculitis, pyoderma gangrenosum
Heart	Pericarditis, premature atherosclerosis, vasculitis, valve disease, and valve ring nodules
Lung	Pleural effusions, interstitial lung disease, bronchiolitis obliterans, rheumatoid nodules, vasculitis
Eye	Keratoconjunctivitis sicca, episcleritis, scleritis, scleromalacia perforans, peripheral ulcerative keratopathy
Neurologic	Entrapment neuropathy, cervical myelopathy, mononeuritis multiplex (vasculitis), peripheral neuropathy
Hematopoietic	Anemia, thrombocytosis, lymphadenopathy, Felty syndrome, large granular lymphocyte syndrome
Kidney	Amyloidosis, vasculitis
Bone	Osteopenia

FIGURE 243-6. Rheumatoid nodules. Large rheumatoid nodules are seen in a classic location along the extensor surface of the forearm and in the olecranon bursa.

Pericardial effusions (Chapter 62) are common (50% by echocardiography) but usually are asymptomatic. Rarely, long-standing pericardial disease may result in a fibrinous pericarditis, and patients may develop constrictive pericarditis (Chapter 62). The incidence of venous thromboembolism is also increased.

Pulmonary Manifestations

Pulmonary manifestations include pleural effusions (Chapter 86), rheumatoid nodules, and parenchymal lung disease. Pleural effusions occur more commonly in men and are usually small and asymptomatic. Rheumatoid nodules may occur in the lung, especially in men (Fig. 243-9) and are usually solid but may calcify, cavitate, or become infected. Rarely, pulmonary nodules rupture and produce a pneumothorax. If patients with rheumatoid arthritis are exposed to coal or silica dust, diffuse nodular densities may occur (Caplan syndrome).

Interstitial lung disease (Chapter 80), usually clinically silent, may affect up to 45% of patients with rheumatoid arthritis.[9] Interstitial lung disease, which rarely may precede joint manifestations, may progress to increasing dyspnea and a honeycomb appearance on radiography. Rarely, bronchiolitis obliterans can be seen, with or without organizing pneumonia.

Ophthalmologic Manifestations

The most common eye manifestation of rheumatoid arthritis is keratoconjunctivitis sicca (dry eyes) from secondary Sjögren syndrome (Chapter 247). Patients may have associated xerostomia (dry mouth), parotid gland swelling, or, occasionally, lymphadenopathy. Scleritis also can occur and may be painful, with progression to thinning of the sclera (manifesting as deep pigment showing through on physical examination) and perforation (scleromalacia perforans). Rarely, tendinitis of the superior oblique muscles can result in double vision (Brown syndrome).

FIGURE 243-7. Rheumatoid nodulosis. In this patient, multiple rheumatoid nodules are present over joints. In some cases, nodules may dominate the clinical picture. Rarely, this may be seen as a side effect of methotrexate therapy.

FIGURE 243-9. Rheumatoid nodules in the lung. Chest radiograph demonstrates discrete rheumatoid nodules in both right and left lower lobes. (Courtesy Dr. Martin Lidsky, Houston, TX.)

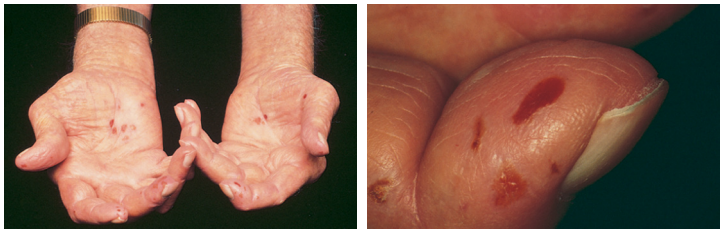

FIGURE 243-8. Small vessel vasculitis. A and B, Rheumatoid vasculitis with small brown infarcts of palms and fingers in chronic rheumatoid arthritis. (Courtesy Dr. Martin Lidsky, Houston, TX.)

Neurologic Manifestations

Peripheral nerve entrapment syndromes, including carpal tunnel syndrome (median nerve at the wrist; Chapter 388) and tarsal tunnel syndrome (anterior tibial nerve at the ankle), are common in rheumatoid arthritis. Vasculitis can lead to a stocking and glove neuropathy or mononeuritis multiplex (Chapter 388). Subluxations at C1-C2 may produce myelopathy (see Fig. 243-2). Rheumatoid nodules in the central nervous system have been described, but they are rare and usually asymptomatic.

Felty Syndrome

Felty syndrome is the triad of rheumatoid arthritis, splenomegaly, and neutropenia. This complication, which is seen in patients with severe rheumatoid factor/ACPA-positive disease but is now rare, may be accompanied by hepatomegaly, thrombocytopenia, lymphadenopathy, and fever.

Some patients who were previously thought to have Felty syndrome have peripheral white blood cell counts dominated by large granular lymphocytes with almost complete absence of neutrophils. This condition is known as the large granular lymphocyte syndrome and is thought to be a low-grade lymphoproliferative disorder characterized by the clonal proliferation of large granular lymphocytes.

DIAGNOSIS

All current treatment paradigms for rheumatoid arthritis stress the early and aggressive use of disease-modifying antirheumatic drugs (DMARDs). Therefore, the importance of accurate early diagnosis cannot be overemphasized.[10]

The distribution of involved joints is a critical clue to the underlying diagnosis. The joints that are involved at presentation are variable; typically, the symptoms start in the small joints of the hands (PIP and MCP joints) and in the toes (MTP joints). Importantly, rheumatoid arthritis usually spares the DIP joints and the small joints of the toes. Later, involvement is more common in larger joints: wrists, knees, elbows, ankles, hips, and shoulders. Although the patient's history of joint symptoms (arthralgia) is important, the diagnosis of rheumatoid arthritis requires the presence of inflammation (swelling, warmth, or both) on examination and/or imaging of the joints.

Rheumatoid arthritis has no single pathognomonic finding on physical examination or laboratory testing. Instead, the diagnosis of rheumatoid arthritis requires a collection of historical and physical features, as well as an alert and informed clinician. Inflammatory changes in the joints may be confirmed using ultrasound or magnetic resonance imaging (MRI) in early disease (Chapter 238).

Classification and Diagnostic Criteria

Classification criteria (Fig. 243-10) now serve as the gold standard for clinical trials and are widely used as diagnostic aids. However, clinicians must consider the duration of symptoms and signs in making a diagnosis and be as confident as possible that another explanation, including many virus-related syndromes, is not the cause of a self-limited polyarthritis that looks identical to rheumatoid arthritis,[11] even including the presence of rheumatoid factor. Such conditions usually persist for only 2 to 3 weeks. Classification criteria for rheumatoid arthritis do not require 6 weeks of disease and give significant weight to the presence of high-titer rheumatoid factor or ACPA positivity.[12] The presence of ACPA antibodies, even in the first few weeks of an inflammatory arthritis, is suggestive of more aggressive rheumatoid arthritis.

Laboratory Findings

The most characteristic laboratory abnormality (Chapter 237) is the presence of rheumatoid factor, which is found in approximately 75% of patients. The presence of rheumatoid factor is strongly associated with more severe articular disease, as well as with essentially all the extra-articular features. However, rheumatoid factor is seen in association with many diseases other than rheumatoid arthritis, particularly in disease processes that induce chronic stimulation of the immune system (Table 243-2).

Anti-citrullinated protein antibodies (the most commonly detected of the anti-modified protein antibodies [AMPAs]) are found in approximately 70% of patients with rheumatoid arthritis, have a high specificity (93 to 98%), may be present years before clinical disease is diagnosed, and are associated with aggressive erosive disease.

Approximately 15% of rheumatoid arthritis patients are negative for both rheumatoid factor and anti-citrullinated protein antibodies (seronegative). Rheumatoid arthritis is also associated with many other autoantibodies, including antinuclear antibodies (≈30%) and antineutrophil cytoplasmic antibodies, particularly of the perinuclear type (≈30%) (Chapter 237).

Many patients with rheumatoid arthritis have an anemia of chronic disease (or anemia of chronic inflammation), and the degree of anemia is proportional to the activity of the disease (Chapter 144). Therapy that controls the disease will normalize the hemoglobin levels. Other causes of anemia

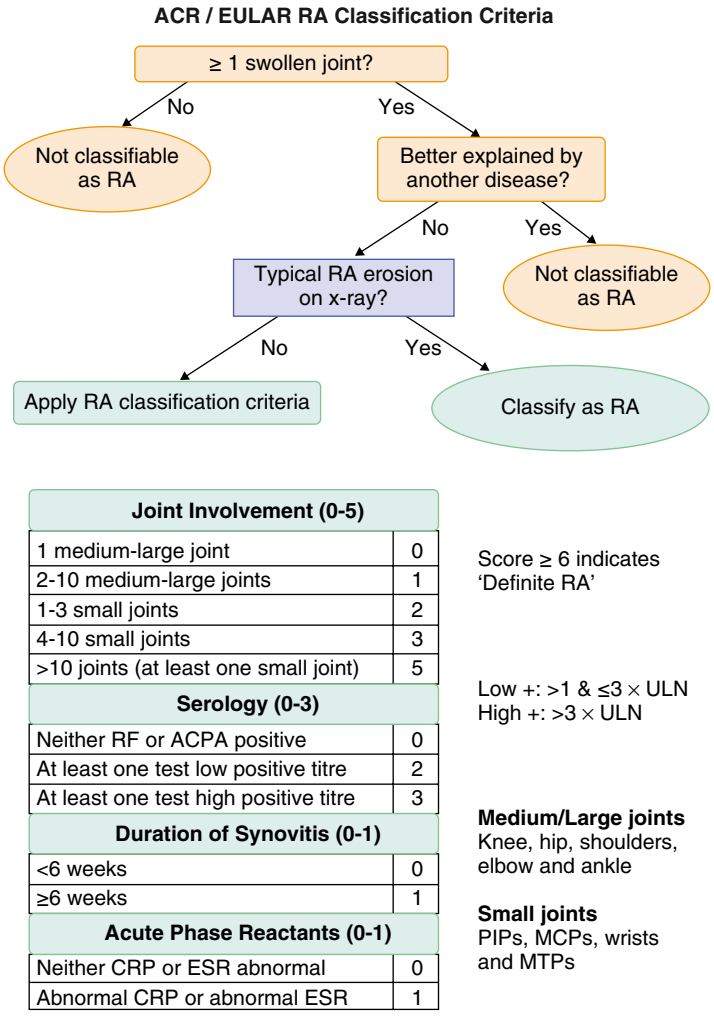

FIGURE 243-10. **American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) classification criteria for rheumatoid arthritis (RA).** The classification criteria are shown as a flow diagram for initial decision making and also in tabular form to calculate American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) classification criteria for rheumatoid arthritis (RA). ACPA = anti-citrullinated protein antibody; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; MCP = metacarpal phalangeal joint; MTP = metatarsal phalangeal joint; PIP = proximal interphalangeal joint; RA = rheumatoid arthritis; RF = rheumatoid factor; ULN = upper limit of normal. (Data from Aletaha D, Neogi T, Silman AJ, et al. 2010 Rheumatoid arthritis classification criteria. An American College of Rheumatology/European League Against Rheumatism collaborative initiative. *Arthritis Rheum*. 2010;62:2569-2581.)

in rheumatoid arthritis include iron deficiency anemia from gastrointestinal blood loss (especially with concomitant use of NSAIDs). Thrombocytosis is common, with platelet counts returning to normal as the inflammation is controlled. Acute phase reactants such as the erythrocyte sedimentation rate and C-reactive protein levels parallel the activity of the disease, and their persistent elevation portends a poor prognosis in terms of both joint destruction and mortality. White blood cell counts may be elevated, normal, or, in the case of Felty syndrome, depressed. Eosinophilia is present in some patients with rheumatoid arthritis.

Synovial fluid in rheumatoid arthritis is characterized by white blood cell counts in the range of 5000 to 100,000/μL, with approximately two thirds of the cells being polymorphonuclear leukocytes. There are no synovial fluid findings that are pathognomonic of rheumatoid arthritis. Pleural fluid in rheumatoid arthritis is characterized by low levels of glucose and low pH and can be confused with empyema.

Differential Diagnosis

The accurate diagnosis of rheumatoid arthritis early in its course, although challenging, is critical if patients are to benefit maximally from therapeutic intervention. Once disease has been present and active for years and the characteristic deformities and radiographic changes have occurred, the diagnosis is all too obvious. Once rheumatoid arthritis has progressed to that point, deformities may no longer be amenable to medical therapy.

TABLE 243-2 DIFFERENTIAL DIAGNOSIS OF RHEUMATOID ARTHRITIS

DISORDER	SUBCUTANEOUS NODULES	RHEUMATOID FACTOR
Viral arthritis (hepatitis B and C, parvovirus, rubella, others)	–	±
Bacterial endocarditis	±	+
Rheumatic fever	+	–
Sarcoidosis	+	+
Reactive arthritis	–	–
Psoriatic arthritis	–	–
Systemic lupus erythematosus	±	+
Primary Sjögren syndrome	–	+
Chronic tophus gout	+	–
Calcium pyrophosphate disease	–	–
Polymyalgia rheumatica	–	–
Osteoarthritis (erosive)	–	–

– = not present; + = frequently present; ± = occasionally present.

Many diseases can mimic rheumatoid arthritis (see Table 243-2). Early in the course of disease, self-limited viral syndromes must be considered, especially hepatitis B and C (Chapter 135), parvovirus (Chapter 342), rubella (infection or vaccination; Chapter 339), and Epstein-Barr virus (Chapter 348). At any time, systemic lupus erythematosus (Chapter 245), psoriatic arthritis (Chapter 244), and reactive arthritis may present differential diagnostic challenges. In the case of these three mimics, a targeted history and examination to elucidate their associated clinical features (e.g., rashes, oral ulcers, nail changes, dactylitis, urethritis, or renal, pulmonary, gastrointestinal, or ophthalmologic involvement) is critical. Especially in elderly patients with fulminant-onset rheumatoid arthritis, remitting rheumatoid factor–negative symmetrical synovitis with pitting edema (the so-called RS3PE syndrome) and paraneoplastic syndromes should be considered. Chronic tophaceous gout (Chapter 252) also may mimic severe nodular rheumatoid arthritis.

Differentiating rheumatoid lung nodules from lung cancer can be problematic, particularly if the lesion is solitary. Therefore, the presence of pulmonary nodules in a patient with rheumatoid arthritis should precipitate an aggressive diagnostic evaluation (Fig. 177-1). Hypothyroidism (Chapter 207) not only causes many rheumatic manifestations but also occurs commonly in conjunction with rheumatoid arthritis and, therefore, should be considered.

TREATMENT

General Measures

Despite many different options, rheumatoid arthritis is a lifelong disease process that has no known cure. Patients with rheumatoid arthritis should be educated about their disease and its treatment. Optimal patient care requires effective ongoing interactions among primary care clinicians and rheumatologists, as well as a multidisciplinary team that can include rheumatology specialist nurses, physical therapists, occupational therapists, and orthopedic surgeons.[A1] Because of the serious nature of the disease, the necessity for rapid introduction and revision of treatments, and the need for expertise in monitoring these therapies, all patients with rheumatoid arthritis should be evaluated early and followed closely by a rheumatologist.

Patients should have an opportunity to spend time with physical therapists and occupation therapists to learn about range-of-motion exercises, joint protection, and assistive devices. Stiffness is relieved by warmth and activity, and reducing or eliminating joint stiffness is a clear goal of therapy.

TABLE 243-3 KEYS TO OPTIMIZE OUTCOME OF TREATMENT OF RHEUMATOID ARTHRITIS

Early, accurate diagnosis
Early DMARD therapy
Strive for remission in all patients
Monitor carefully for treatment toxicities
Consider and treat comorbid conditions*

*Important comorbid conditions include cardiovascular disease, increased susceptibility to infections, and osteoporosis.
DMARD = disease-modifying antirheumatic drug.

The goal of therapy, which is disease remission (Table 243-3) or very low disease activity, should always be kept in mind.[13] When rheumatoid arthritis is treated early, remission is possible in over 50% of patients and low disease activity in at least another 35%. However, continued response requires the ongoing use of disease-modifying anti-rheumatic drugs (DMARDs), which essentially all rheumatoid arthritis patients should receive. In many patients, combinations of different DMARDs (conventional and biologic) are necessary for optimal control. Therapy should be escalated rapidly to ensure maximal suppression of disease while minimizing toxicity and expense.

Medical Therapy

Three types of medical therapies (Table 243-4) are used for rheumatoid arthritis: NSAIDs, glucocorticoids, and DMARDs (conventional, biologic and targeted synthetic). Initial therapy should always include a DMARD.[14]

Nonsteroidal Anti-inflammatory Drugs

NSAIDs (Table 26-4) are important for the symptomatic relief they provide, but they play only a minor role, if any, in altering the underlying disease process. Therefore, NSAIDs should rarely, if ever, be used to treat rheumatoid arthritis without the concomitant use of DMARDs.

Cyclooxygenase-2 (COX2)-selective agents, which are less likely to cause gastrointestinal bleeding, have been a popular choice for patients with rheumatoid arthritis, but evidence linking these agents to increased cardiovascular toxicity is particularly troubling for patients with rheumatoid arthritis, who are already at high risk for myocardial infarction and stroke. In a randomized clinical trial, however, the cyclooxygenase-2 (COX-2) selective NSAID, celecoxib, was non-inferior compared with naproxen or ibuprofen in terms of cardiovascular outcomes.[A2] If COX2-selective agents are used, they should be kept at a low dose. Consideration should be given to low-dose aspirin prophylaxis, but this therapy may increase the gastrointestinal toxicity of NSAIDs. The concomitant use of a proton pump inhibitor (Table 124-1) should be considered in all patients with rheumatoid arthritis who are taking NSAIDs. Additionally, the potential for NSAIDs to decrease renal blood flow and to increase blood pressure should be kept in mind.

Glucocorticoids

Glucocorticoids (Chapter 28) provide dramatic and rapid symptomatic improvement in patients with rheumatoid arthritis, and they also significantly decrease its radiographic progression. However, the toxicities of long-term therapy are extensive and potentially devastating, including a 25% increased risk of serious infection with doses as low as 5 mg daily and a doubling of risk at 5 to 10 mg daily[15] (Chapter 28), so these drugs must be used carefully (Table 243-5).

Because of their rapid onset of action, glucocorticosteroids are ideally suited to help control the inflammation in rheumatoid arthritis while the much slower-acting DMARDs start to work. Glucocorticoids should rarely, if ever, be used without concomitant DMARD therapy.

Prednisone, which is the most commonly used glucocorticoid, should rarely be used in doses higher than 10 mg/day to treat the articular manifestations of rheumatoid arthritis. At this dose at the start of methotrexate-based treatment, the addition of prednisone reduces erosive joint damage, disease activity, physical disability, and the use of biologic treatment at 2 years. The dose should be slowly tapered to the lowest effective dose, and concomitant DMARD therapy should be adjusted to make this possible. For example, 5 mg of prednisolone daily is effective add-on therapy in patients over age 65 years.[A3]

Some rheumatologists use intramuscular depot injection of glucocorticoids to ensure delivery and manage initial DMARD escalation or transient flare. Intra-articular glucocorticoid injection is also useful, and ultrasound guidance is helpful for difficult-to-access joints.

The goal is to have all patients off or on very low doses of glucocorticoids with their disease controlled by DMARDs. However, higher doses of glucocorticoids may be necessary to treat extra-articular manifestations, especially vasculitis and scleritis.

TABLE 243-4 TREATMENT OPTIONS FOR RHEUMATOID ARTHRITIS

MEDICATION	DOSE
NONSTEROIDAL ANTI-INFLAMMATORY DRUGS*	
Celecoxib	100 mg PO twice daily or 200 mg PO daily
Diclofenac/misoprostol	50 mg/200 mg PO 2-4 times daily
Etodolac	300 mg PO 2 or 3 times daily; or 400 or 500 mg PO twice daily
Ibuprofen	400 mg PO four times daily
Ketoprofen	75 mg PO three times daily; or 50 mg PO four times daily
Naproxen	500 mg PO twice daily
Naproxen/esomeprazole	375 mg/20 mg or 500 mg/20 mg PO twice daily
Tolmetin	400 mg PO three times daily
GLUCOCORTICOIDS*	
Prednisone	5-10 mg PO once daily
DISEASE-MODIFYING ANTIRHEUMATIC DRUGS (DMARDs)	
Conventional DMARDs	
Hydroxychloroquine	200-400 mg PO daily (5 mg/kg)
Leflunomide	10-20 mg PO once daily
Methotrexate	7.5-25 mg PO† once weekly (PO or SQ)
Sulfasalazine	500 mg PO once or twice daily for first 2 weeks; then 2 g daily in two evenly divided doses
Azathioprine	1 mg/kg (50-100 mg) PO as a single dose or twice daily; may be increased up to 2.5 mg/kg
Minocycline	100 mg PO twice daily
Biologic DMARDs	
Abatacept	500-1000‡ mg IV at 0, 2, and 4 weeks, then every 4 weeks§
Adalimumab	40 mg SQ every other week
Certolizumab	400 mg SQ at weeks 2 and 4, followed by 200 mg every other week
Etanercept	50 mg SQ once weekly
Golimumab	50 mg SQ once a month¶
Infliximab	In conjunction with methotrexate, 3-5 mg/kg IV at 0, 2, and 6 weeks, then every 4-8 weeks
Rituximab	In combination with methotrexate, two 1000-mg IV infusions separated by 2 weeks (one course) every 16-24 weeks
Tocilizumab	4 mg/kg IV every 4 weeks followed by 8 mg/kg every 4 weeks**
Targeted Synthetic DMARDs	
Tofacitinib	5 mg PO twice daily
Baricitinib	2 or 4 mg PO once daily
Upadacitinib	15 mg PO once daily

*Initial treatment should always include a DMARD; see text.
†May be administered SQ to reduce side effects and when higher doses are needed.
‡500 mg if <60 kg; 750 mg if 600-100 kg; 1000 mg if >100 kg.
§May be administered SQ once weekly with or without an IV loading dose.
¶May be administered IV at a dose of 2 mg/kg at weeks 0 and 4, then every 8 weeks.
**May be administered SQ at a starting dose of 162 mg every other week if <100 kg, or 162 mg every week if >100 kg.
DMARD = disease-modifying antirheumatic drug; PO = orally; IV = intravenously; SQ = subcutaneously.

TABLE 243-5 GUIDELINES FOR USE OF GLUCOCORTICOIDS

Avoid use of glucocorticoids without DMARDs
Prednisone, >10 mg/day, is rarely indicated for articular disease
Taper to the lowest effective dose and stop if possible.
Toxic risk is associated with average dose >8 mg daily
Use as "bridge therapy" until DMARD therapy is effective
Remember prophylaxis against osteoporosis
Can be used parenterally as well as orally

DMARD = disease-modifying antirheumatic drug.

In all patients receiving glucocorticoids, meticulous measures should be taken to prevent osteoporosis. Bisphosphonates (Chapter 225) are particularly effective but are contraindicated in women of childbearing age.

Disease-Modifying Antirheumatic Drugs

DMARDs are a group of medications that have the ability to halt the disease process in the synovium and to modify or change the disabling potential of rheumatoid arthritis.[16,17] These drugs also can halt or slow radiographic progression of the disease.

Conventional Disease-Modifying Antirheumatic Drugs

Included in this group of medications are methotrexate, sulfasalazine (Azulfidine), gold, antimalarials (hydroxychloroquine and others), leflunomide, azathioprine, and minocycline. Of these agents, methotrexate and hydroxychloroquine are still widely used, whereas sulfasalazine is also used in Europe and Asia. These conventional DMARDs require 2 to 6 months to exert their maximal effect, and all require monitoring to detect early adverse events (Table 243-6). Monitoring of the serum drug levels of biologic agents may be useful in patients in remission, because higher blood levels may predict a longer relapse-free period.[18]

These DMARDs are effective in treating both early and more advanced rheumatoid arthritis. Methotrexate is generally recommended as the initial anchor conventional DMARD. However, the selection of the best initial therapy for each patient depends on the concerns of the patient and physician about toxicity and monitoring issues, as well as the activity of disease and the presence of comorbid conditions. The critical issue is not which DMARD to start first but rather starting the DMARD early in the disease process.

Methotrexate

Methotrexate should be the initial DMARD for most patients; it is economical, serious toxicities are rare, and when used in combination it makes essentially all other DMARDs work better. Methotrexate is contraindicated in pregnancy and in patients with significant renal impairment. Relative care should be taken in patients who have diabetes. Methotrexate is effective in slowing radiographic progression and is given orally as a single weekly dose ranging from 5 to 25 mg. Oral absorption of methotrexate is variable, and subcutaneous injections, which are the norm in some clinical practices, are often effective when oral treatment is not. Side effects of methotrexate (Chapter 28) include oral ulcers, nausea, hepatotoxicity, bone marrow suppression, and pneumonitis. With the exception of pneumonitis, these toxicities respond to dose adjustments. Monitoring of blood counts and liver blood tests (albumin and aspartate aminotransaminase [AST] or alanine aminotransferase [ALT]) should be done every 3 mo, with adjustments in the dose of methotrexate as needed. Renal function is critical for clearance of methotrexate, and previously stable patients may experience severe toxicities if renal function deteriorates. Pneumonitis, although rare, is less predictable and can be fatal, particularly if the methotrexate is not stopped or is restarted. Folic acid, 1 to 4 mg/day, or 5 mg per week, can significantly decrease most methotrexate toxicities without interfering with efficacy.

If methotrexate alone does not sufficiently control disease, it may be combined with other DMARDs. Methotrexate in combination with virtually any of the other DMARDs (conventional biologic or targeted synthetic) is more effective than either drug alone.

TABLE 243-6 CAVEATS FOR MONITORING DISEASE-MODIFYING ANTIRHEUMATIC DRUG THERAPIES*

MEDICATION	CAVEATS
Prednisone	Use as bridge to effective DMARD therapy, consider prophylaxis for osteoporosis (see Table 243-5)
Hydroxychloroquine	Keep dosage lower than 5.0 mg/kg/day. Yearly eye checkup by ophthalmologist after 5 yr of therapy
Sulfasalazine	CBC for neutropenia, initially every month, then every 6 mo
Methotrexate	CBC and AST/ALT every 8-12 wk when dose is stable. Many toxicities respond to folic acid or small dose reduction. If pneumonitis, stop and do not restart. Decreasing renal function may precipitate toxicities. Absolute contraindication in pregnancy
Leflunomide	CBC and AST/ALT every 4-8 wk; long half-life may require cholestyramine washout; absolute contraindication in pregnancy
TNF inhibitors	If fevers or infectious symptoms of any kind, stop until symptoms resolve; aggressively evaluate and treat possible infections. May precipitate congestive heart failure, demyelinating syndromes, or lupus-like syndromes
IL-6 receptor inhibitors	If fevers or infectious symptoms of any kind, stop until symptoms resolve; aggressively evaluate and treat possible infections. Avoid if history of perforation or diverticulitis. Note lipids will rise within 3 mo of therapy commencement
JAK inhibitors	Watch for elevation of LFTs, creatinine kinase, creatinine levels and adhere to regional monitoring requirements. Care if at risk of or history of thrombosis. Risk of herpes zoster is considered higher than with other DMARD classes

*Patients receiving DMARDs, both conventional and biologic, should be monitored by a rheumatologist.

ALT = alanine aminotransferase; AST = aspartate aminotransferase; CBC = compete blood count; DMARD = disease-modifying antirheumatic drug; GI = gastrointestinal; IL = interleukin; JAK = Janus kinase; LFTs = liver function tests; TNF = tumor necrosis factor.

Leflunomide

Leflunomide, a pyrimidine antagonist, has a very long half-life and is most commonly started at 10 to 20 mg/day orally. Diarrhea is the most common toxicity and responds to dose reduction. Doses of leflunomide of 10 to 20 mg three to five times per week are frequently used. Also, because of the long half-life and teratogenic potential of leflunomide, women wishing to become pregnant who have previously received leflunomide, even if therapy was stopped years ago, should have blood levels drawn. If toxicity occurs or if pregnancy is being considered, leflunomide can be rapidly eliminated from the body by treatment with cholestyramine. Laboratory monitoring for hematologic and hepatic toxicity should be done during treatment with leflunomide, as recommended for methotrexate.

Antimalarial Drugs

The antimalarial drugs hydroxychloroquine and chloroquine are frequently used to treat rheumatoid arthritis. They have the least toxicity of any of the DMARDs and do not require monitoring of blood tests. Yearly monitoring by an ophthalmologist after 5 years of therapy is recommended to detect any signs of retinal toxicity (rare). Hydroxychloroquine is the most commonly used preparation and is given orally at 200 to 400 mg/day (5 mg/kg). These drugs are frequently used in combination with other DMARDs, particularly methotrexate. Hydroxychloroquine decreases cholesterol levels and decreases the incidence of diabetes in patients with rheumatoid arthritis.

Sulfasalazine

Sulfasalazine is an effective treatment when given in doses of 1 to 3 g/day. Monitoring of blood counts, particularly white blood cell counts, in the first 6 mo is recommended. Sulfasalazine and hydroxychloroquine are often combined with methotrexate, a regimen referred to as triple therapy, which has efficacy similar to the combination of a TNF inhibitor and methotrexate and is more economical.

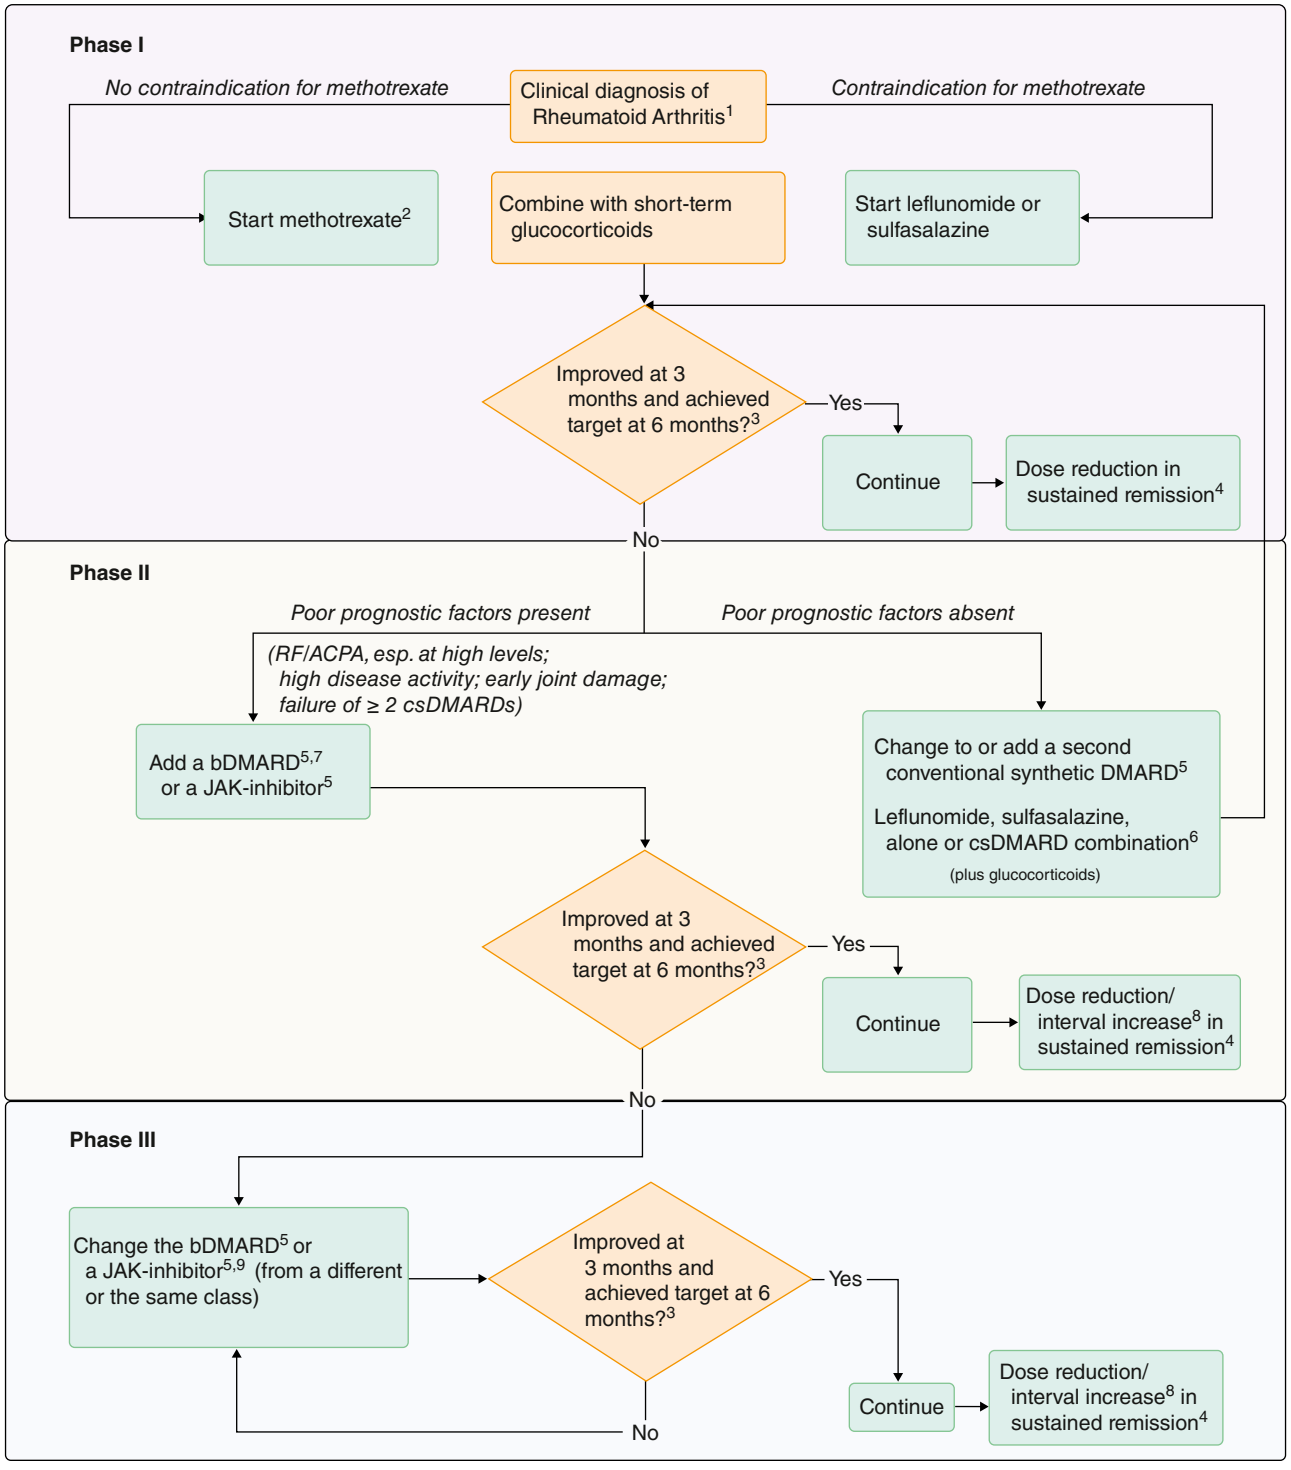
Minocycline

Minocycline 100 mg twice daily is an effective treatment for rheumatoid arthritis, particularly when used in early rheumatoid factor–positive disease. Chronic therapy (>2 years) with minocycline may lead to cutaneous hyperpigmentation, which reverses when the drug is stopped. Minocycline has also been associated with drug-induced systemic lupus erythematosus (Chapter 245).

Biologic Disease-Modifying Antirheumatic Drugs

Biologic agents can be directed against TNF (etanercept, infliximab, adalimumab, golimumab, and certolizumab), the IL-6 receptor (tocilizumab and sarilumab), and IL-1 (anakinra). In practice IL-1 inhibitors are rarely used in the treatment of rheumatoid arthritis. Additionally, monoclonal antibodies that deplete B cells (anti-CD20, rituximab)[A4] and that block the second signal for T-cell activation (abatacept) are effective treatments for rheumatoid arthritis, but tocilizumab appears to be superior to rituximab.[A5]

All patients with rheumatoid arthritis receiving biologic therapies should be monitored by a rheumatologist, and all their physicians should be aware of the risk for infections that are often atypical.[19] In patients who have active disease despite methotrexate, all the biologics decrease disease activity and then slow radiographic progression when combined with methotrexate. Early treatment with tocilizumab plus methotrexate results in greater sustainable clinical, functional, and radiographic benefits than methotrexate alone, with acceptable safety and tolerability, in early erosive rheumatoid arthritis.



1. *2010/ACR-EULAR classification criteria can support early diagnosis.*
2. *"Methotrexate should be part of the first treatment strategy;" combination therapy with csDMARDs is not preferred by the Task Force; starting with methotrexate does not exclude its use in combination with other csDMARDs, although more adverse events without added benefit are to be expected, especially if methotrexate is combined with glucocorticoids.*
3. *The treatment target is clinical remission according to ACR-EULAR definitions or, if remission is unlikely to be achievable, at least low disease activity; the target should be reached after 6 months, but therapy should be adapted or changed if insufficient improvement (less than 50% of disease activity) is seen after 3 months.*
4. *Sustained remission: ≥ 6 months based on ACR/EULAR index or Boolean remission.*
5. *Consider contraindications and risks.*
6. *The most frequently used combination comprises methotrexate, sulfasalazine, and hydroxychloroquine.*
7. *TNF-inhibitors (adalimumab, certolizumab, etanercept, golimumab, infliximab, including EMA/FDA approved bsDMARDs), abatacept, IL-6R inhibitors, or rituximab (under certain conditions); in patients who cannot use csDMARDs as comedication, IL6-inhibitors and tsDMARDs have some advantages.*
8. *Dose reduction or interval increase can be safely done with all bDMARDs and tsDMARDs with little risk of flares; stopping is associated with high flare rates; most but not all patients can recapture their good state upon re-institution of the same bDMARD/tsDMARD.*
9. *Efficacy and safety of bDMARDs after JAK-inhibitor failure is not fully known; also, efficacy and safety of an IL-6 pathway inhibitor after another one has failed is currently unknown. Efficacy and safety of a JAK-inhibitor after insufficient response to a previous JAK-inhibitor is unknown.*

FIGURE 243-11. Recommendations for the management of rheumatoid arthritis. ACPA = anti-citrullinated peptide antibody; DMARD = disease-modifying antirheumatic drug; JAK = Janus kinase; RF = rheumatoid factor. (From Smolen JS, Landewé RBM, Bijlsma JWJ, et al. EULAR recommendations for the management of rheumatoid arthritis with synthetic and biological disease-modifying antirheumatic drugs: 2019 update. *Ann Rheum Dis*. 2020;79:685-699.)

However, standard-dose and high-dose biologic drugs (with or without traditional DMARDs) are associated with an increase in serious infections,[A6] especially tuberculosis (Chapter 299); pre-treatment screening for latent tuberculosis is mandatory. Biologic agents also should not be used in combination with each other because they significantly increase the risk of infections (see Chapter 29).

Targeted Synthetic Disease-Modifying Antirheumatic Drugs

Tofacitinib, given orally at a dose of 5 mg twice daily, is effective as initial DMARD therapy when combined with methotrexate in patients who have had incomplete responses to methotrexate or who have failed to improve with TNF inhibitors. The complete blood count and liver function tests should be monitored. Additional toxicity concerns include infections, including tuberculosis, malignancies, cardiovascular events, and reactivation of herpes zoster.

Baricitinib is effective in patients whose rheumatoid arthritis has not responded to a DMARD.[A7] Furthermore, baricitinib is better than placebo or adalimumab for patients who had inadequate response to methotrexate.[A8]

Emerging drugs that target distinct members of the JAK family include upadacitinib (15 mg daily), which is a relatively selective agent that is effective either as monotherapy or when added to other DMARDs,[A9] filgotinib (100 to 200 mg daily), which is similarly effective in patients who have an inadequate response to other DMARDs or are intolerant of them,[A10] and olokizumab, which is effective when added to methotrexate therapy.[A11]

The Order of Therapy in Rheumatoid Arthritis

The order of therapeutic choices for the treatment of rheumatoid arthritis continues to evolve (Fig. 243-11). DMARDs generally must be continued at their full dose to maintain their efficacy.[A12] Treatment is best individualized within these general guidelines by an experienced specialist.

Treatment of Underlying Conditions and Complications

Optimal care of patients with rheumatoid arthritis requires recognition of the associated comorbid conditions, including an increased risk for cardiovascular death, osteoporosis, infections (especially pneumonia), and certain cancers such as lymphomas and lung cancers.

Neck Complications

In patients with neck symptoms, neck flexion and extension films of the cervical spine should be obtained to look for significant subluxation.[20] Subluxation is often an indication for corrective surgery. When patients develop stridor as a result of severe involvement of the cricoarytenoid joint, emergent tracheotomy may be life-saving.

Felty Syndrome

Most patients with Felty syndrome do not require special therapy; instead, treatment directed toward their severe rheumatoid arthritis usually improves the white blood cell counts. If severe (<500 cells/μL) neutropenia (Chapter 153) is accompanied by recurrent bacterial infections or chronic, nonhealing leg ulcers, splenectomy may very rarely be indicated. In the presence of rheumatoid arthritis or Sjögren syndrome, large granular lymphocyte syndrome has a good prognosis, with the neutropenia often responding dramatically to therapies, particularly methotrexate.

Cardiovascular Disease

Cardiovascular disease accounts for much of the excess mortality in rheumatoid arthritis, probably because of an association between chronic inflammation and cardiovascular disease.[21] Methotrexate, tofacitinib, and TNF inhibitors can significantly decrease cardiovascular mortality, whereas tocilizumab and JAK inhibitors cause a rise in serum cholesterol levels. Patients with rheumatoid arthritis also should be aggressively treated for their cardiovascular risk factors (Chapters 39, 64, and 190).

Other Associated Diseases

Osteoporosis (Chapter 225) is common in patients with rheumatoid arthritis, and its early treatment results in long-term dividends. Patients with rheumatoid arthritis are at an increased risk for infections, and some forms of treatment further increase this risk.[22] Patients should be cautioned to seek early medical attention for even minor symptoms suggestive of infection, especially if receiving biologic therapy. All patients with rheumatoid arthritis should receive a pneumococcal vaccine, yearly influenza vaccinations (Chapter 15), and one of the zoster vaccinations.

Patients with rheumatoid arthritis have an increased risk for lymphoma. Occasionally, B-cell lymphomas (Chapter 171) are associated with immunosuppression and regress after immunosuppression is discontinued. Patients with rheumatoid arthritis have significantly decreased risk of developing colon cancer, probably because of chronic inhibition of COX by NSAIDs.

PROGNOSIS

Rheumatoid arthritis is not a benign disease and is not limited to the joints. Once established, it is a lifelong progressive disease that produces significant morbidity in most patients and premature mortality in many. With modern effective treatment, however, all-cause mortality in patients with rheumatoid arthritis is now similar to the general population. The aggressive use of disease-modifying agents and biologic agents, if needed, also is associated with substantial reductions in disability.

Patients who are rheumatoid factor– or anti-citrullinated protein antibody–positive and patients who are positive for the shared epitope have a worse prognosis, with more erosions and more extra-articular disease (see E-Table 243-1). The HLA-DRB1 locus, which is associated with disease susceptibility, may also be associated with radiologic severity, mortality, and treatment response. Once deformities are found on examination or erosions on radiography, the damage is largely irreversible. Erosions usually occur in the first 1 to 2 years, and the rate of radiographic damage can be reduced by early therapy.

244 SPONDYLOARTHRITIS

ROBERT D. INMAN AND PROTON RAHMAN

COMMON FEATURES OF SPONDYLOARTHRITIS

DEFINITION

Spondyloarthritis encompasses a group of clinical syndromes that are linked in terms of disease manifestations and genetic susceptibility. The clinical subsets most commonly recognized are ankylosing spondylitis, psoriatic arthritis, reactive arthritis, and enteropathic arthritis (Fig. 244-1). Broadly, spondyloarthritis is grouped into two subsets based on the location of predominantly affected joints: axial spondyloarthritis (dominated by back symptoms) and peripheral spondyloarthritis (dominated by peripheral joint symptoms). The Assessment of SpondyloArthritis international Society further classified axial spondyloarthritis into radiographic axial spondyloarthritis (commonly referred to as ankylosing spondylitis), in which structural damage is visible on plain radiographs of the sacroiliac joint, and nonradiographic axial spondyloarthritis, in which no structural damage to the sacroiliac joints is seen on plain radiographs.

EPIDEMIOLOGY AND PATHOBIOLOGY

Family studies note excessive clustering of the same disease entity among family members as well as common features among the distinct subsets. The impression from such studies is a shared common path of immunogenetic susceptibility, with further genetic and environmental influences that lead to characteristic clinical subsets. For example, enteropathic arthritis may occur in one family, whereas psoriatic arthritis may occur in another family.

Genetic Susceptibility

In genomic studies of families with spondyloarthritis, particularly ankylosing spondylitis and psoriatic arthritis, the strongest association is with HLA-B27.[1] About 90% of patients with ankylosing spondylitis are B27-positive, so to a certain extent it may be necessary but not sufficient for the disease. Magnetic resonance imaging (MRI) studies in asymptomatic B27-positive individuals indicate a much higher prevalence of sacroiliitis than previously recognized. Spondyloarthritis may be as common as rheumatoid arthritis.

The major histocompatibility complex (MHC), on the short arm of chromosome 6 in humans, is one of the most polymorphic regions of the human genome. This is particularly so for the B locus, which constitutes part of the class 1 MHC genes in this complex. More than 200 different alleles have been detected at this locus, of which B27 is just one. As with all HLA alleles, there is codominant expression of B locus genes, such that most individuals who are B27-positive are heterozygous for the B locus. There appears to be little clinical or prognostic significance associated with the less common homozygous B27 state.

It is clear that HLA is strongly associated with spondyloarthritis, yet the prevalence of HLA-B27 varies widely in different racial and ethnic clusters around the world. It is virtually absent in aboriginal populations in Australia, occurs in 1% of the population in Japan, in 7% in northern European countries and in North American White populations, and in 50% of some of the native tribes in western Canada.

Of the more than 30 subtypes of B27, HLA-B2705 is regarded as the primordial subtype, with variability developing over time on the basis of alterations in genomic DNA. Some subtypes, notably B2706 and B2709, do not seem to confer increased susceptibility to the development of ankylosing spondylitis. This observation has led to a search for arthritogenic peptides that are presented by the disease-associated subtypes such as B2705 and B2704, but not by the non–disease-associated subtypes. To date, no simple peptide-susceptibility relationship has been demonstrated.

Polymorphisms in the endoplasmic reticulum aminopeptidase-1 (*ERAP1*) gene on chromosome 5 are the second strongest genetic risk factor for ankylosing spondylitis after HLA-B27, and the association with ankylosing spondylitis and *ERAP1* is restricted to patients with HLA-B27+ ankylosing spondylitis, thereby suggesting a gene–gene interaction. ERAP plays a key role in trimming peptides in the endoplasmic reticulum before loading these peptide complexes onto a nascent class I MHC molecule. This finding continues to attribute a central role to MHC class I peptide presentation in the pathogenesis of ankylosing spondylitis.

Additional genetic markers outside the MHC region include the *IL-23R* gene on chromosome 1, which is associated with ankylosing spondylitis, inflammatory bowel disease, and psoriasis. Overall, more than 100 genes confer susceptibility to ankylosing spondylitis, but with the notable exception of HLA-B27, the odds ratio for each is modest.

At the level of joint histopathology, sites of chronic inflammation in rheumatoid arthritis are associated with erosions, but in spondyloarthritis, such sites are associated with new bone formation. This distinction suggests a fundamental difference in the cytokine profile in the microenvironment of the joint. Synovial histopathology in spondyloarthritis is characterized by abundant neutrophils, macrophages, and hypervascularity, whereas in rheumatoid arthritis, the prominent features are lymphoid aggregates, dendritic cells, lining cell hyperplasia, and citrullinated proteins. These differences suggest that spondyloarthritis reflects a fundamental alteration in innate immunity, whereas rheumatoid arthritis reflects dysregulation of adaptive immunity (Chapter 35).

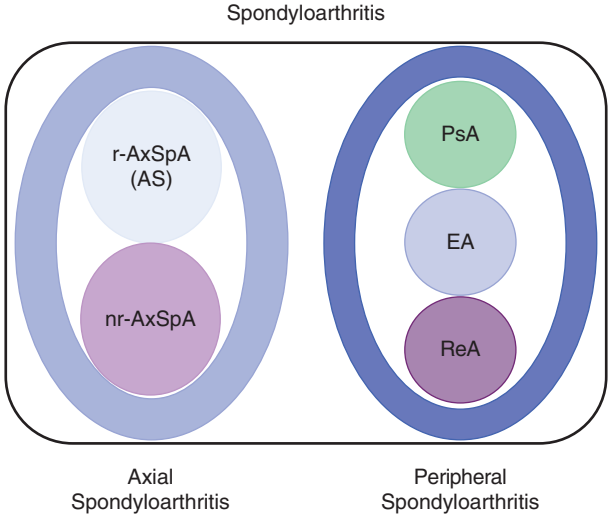

FIGURE 244-1. Schematic relationships among the different spondyloarthritis (SpA) subsets. Ankylosing spondylitis (AS), now referred to radiographic axial SpA, is considered the classic SpA, and nonradiographic axial SpA is the other subset that encompasses the essential features of axial SpA. Psoriatic arthritis (PsA), enteropathic arthritis (EA), and reactive arthritis (ReA) are a distinct subset of peripheral spondyloarthritis and share overlapping features with axial SpA. Many patients have clinical features of SpA but do not meet the diagnostic criteria for any of the five defined subsets and are termed peripheral spondyloarthritis.

CLINICAL MANIFESTATIONS

Common features among the clinical subsets of spondyloarthritis both link them with and distinguish them from rheumatoid arthritis (Chapter 243), which is the other major cause of chronic polyarthritis. Spondyloarthritis has a strong predilection for the spine, in particular the sacroiliac joints, with a tendency for new bone formation at sites of chronic inflammation to cause joint ankylosis. When peripheral arthritis occurs, it is commonly in the lower extremity and asymmetrical. There is a predilection for involvement at sites where tendon inserts into bone (entheses), so enthesitis is one of the most specific clinical manifestations of spondyloarthritis.

A predilection for ocular inflammation, particularly acute anterior uveitis, is a common feature of spondyloarthritis. Uveitis may occur in the same susceptible population of patients even in the absence of joint involvement. Finally, all spondyloarthritis subsets have an association with the class I HLA allele B27, with the strength of the association varying somewhat among them.

DIAGNOSIS

Classification criteria (Table 244-1) emphasize the common clinical features—namely, inflammatory spinal pain or asymmetrical lower extremity synovitis. To fulfill the criteria for axial spondyloarthritis, patients must have chronic back pain for at least 3 months and starting prior to age 45 years. Sacroiliitis confirmed by imaging is an important criterion, and it is referred to as radiographic axial spondyloarthritis when structural damage can be detected by plain radiographs. When active inflammation is detected only by MRI, it is referred to as non-radiographic axial spondyloarthritis. Nonradiographic axial spondyloarthritis can also be defined by the presence of the HLA-B27 allele and two additional features of spondyloarthritis.

ABSTRACT

Spondyloarthritis encompasses a group of clinical syndromes that are linked in terms of disease manifestations and genetic susceptibility. The common clinical subsets are ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and enteropathic arthritis. Immune profiling has highlighted common pathways in cellular immunity in these conditions. Biologic therapies have improved the outlook for these patients, but curative therapies are still being sought.

KEYWORDS

spondyloarthritis
ankylosing spondylitis
psoriatic arthritis
reactive arthritis
enteropathic arthritis

Several distinct features differentiate spondyloarthritis from rheumatoid arthritis, the other main contributor to the differential diagnosis of chronic polyarthritis (Table 244-2). Imaging is often critical for making a diagnosis of axial spondyloarthritis or peripheral spondyloarthritis.[2,3] Useful clinical features include sex predilection, HLA association, pattern of joint involvement, and presence of rheumatoid factor, which becomes the serologic distinction between seropositive rheumatoid arthritis and seronegative spondyloarthritis.[4]

CLINICAL SUBSETS OF THE SPONDYLOARTHROPATHIES

Ankylosing Spondylitis

EPIDEMIOLOGY

Ankylosing spondylitis, now referred to as radiographic axial spondyloarthritis, is the most common inflammatory disorder of the axial skeleton. Ankylosing spondylitis occurs in about 0.2% of the general population, in about 2% of the B27-positive population, and in about 20% of B27-positive individuals with an affected family member.[5] The male-to-female ratio historically has ranged from 2.5 : 1 to 5 : 1, but recent epidemiologic studies suggest a lower ratio.

PATHOBIOLOGY

Molecular mimicry has been hypothesized in the pathogenesis of ankylosing spondylitis because of the degree of sequence homology between B27 and several candidate gram-negative enteric bacteria, but the significance of such homology remains unresolved. B27 is distinctive in its propensity to misfold in the endoplasmic reticulum, where it may induce a pro-inflammatory cascade called the unfolded protein response. Furthermore, B27 may have a distinct tendency to form heavy-chain homodimers at the cell surface.

TABLE 244-1 SPONDYLOARTHRITIS INTERNATIONAL SOCIETY CLASSIFICATION CRITERIA FOR AXIAL SPONDYLOARTHRITIS

A. Chronic back pain starting before age 45 years and persisting for >3 months
AND EITHER
B. Sacroiliitis on a plain radiograph (definite radiographic sacroiliitis according to modified New York criteria [see Table 244-3]) or on magnetic resonance imaging (active [acute] inflammation highly suggestive of sacroiliitis associated with spondyloarthritis) PLUS 1 other criterion
OR
C. HLA-B27 positivity PLUS 2 other criteria

OTHER CRITERIA

- Arthritis
- CRP level elevated
- Crohn disease/ulcerative colitis
- Dactylitis
- Enthesitis (heel)
- Family history of spondyloarthritis
- HLA-B27 positive
- Inflammatory back pain
- NSAIDs provide a good response
- Psoriasis

CRP = C-reactive protein; HLA = human leukocyte antigen; MRI = magnetic resonance imaging; NSAIDs = nonsteroidal anti-inflammatory drugs.

For full details see Rudwaleit M, van der Heijde D, Landewé R, et al. The development of Assessment of SpondyloArthritis international Society classification criteria for axial spondyloarthritis (part II): validation and final selection. *Ann Rheum Dis*. 2009;68:777-783.

B27 transgenic rats spontaneously develop pathology that is strikingly similar to human spondyloarthritis, so B27 itself may be the critical genetic factor in disease pathogenesis. These animals demonstrate pathology similar to that of Crohn disease in the gastrointestinal tract. Of interest, if such animals are raised in a germ-free environment, there is a marked reduction in joint disease, thereby implying a dynamic interrelationship between microbial triggers and background host genes.[6]

CLINICAL MANIFESTATIONS

Ankylosing spondylitis typically begins in young adulthood, but symptoms may arise in adolescence or earlier. Up to 15% of children with juvenile idiopathic arthritis are classified as having juvenile ankylosing spondylitis. During the adolescent years there is an increasing prevalence of radiographic sacroiliitis, with a significant proportion of patients manifesting this feature by the end of the teenage years. At the other end of the age spectrum, a small number of patients with late-onset ankylosing spondylitis may have sacroiliitis and oligoarthritis. The axial involvement and asymmetrical lower extremity involvement may serve to differentiate such patients from patients with late-onset rheumatoid arthritis, although there may be overlapping clinical features.

The classic manifestation of ankylosing spondylitis is the onset of low back pain that persists for more than 3 months, is accompanied by early-morning stiffness, and is typically improved by exercise but not by rest (Table 244-3). Some experts include a response to NSAID therapy as an additional feature that differentiates ankylosing spondylitis from mechanical low back pain. Back pain that awakens the patient from sleep is often a clue to inflammatory back pain that may have been misdiagnosed as the pain of degenerative disc disease (Chapter 369), which is a much more common cause of low back pain in the population at large.

The pain typically occurs in the region of the sacroiliac joints, with or without slight radiation to the buttock area. Midthoracic pain and cervical pain, particularly at night, are less common but strongly suggest inflammatory back pain when they occur. Fatigue is also a suggestive symptom and is often a major concern for the typical young male patient who has a high functional target in terms of sports and recreation. If the inflammation is inadequately controlled, stiffness may persist most of the day and progress to loss of mobility and flexibility.

TABLE 244-3 MODIFIED NEW YORK CRITERIA FOR ANKYLOSING SPONDYLITIS

CLINICAL CRITERIA
Low back pain and stiffness for >3 mo that improve with exercise but are not relieved by rest
Limitation of motion of the lumbar spine in both sagittal and frontal planes
Limitation of chest expansion
RADIOLOGIC CRITERIA
Sacroiliitis: grade ≥2 bilateral or grade 3 or 4 unilateral
GRADING
Definite AS if the radiologic criterion is associated with at least one clinical variable
Probable AS if:
The three clinical criteria are present
The radiologic criterion is present without the clinical criteria

AS = ankylosing spondylitis.

TABLE 244-2 DIFFERENTIAL DIAGNOSIS OF CHRONIC POLYARTHRITIS

FEATURE	RHEUMATOID ARTHRITIS	ANKYLOSING SPONDYLITIS	ENTEROPATHIC ARTHRITIS	PSORIATIC ARTHRITIS	REACTIVE ARTHRITIS
Male-female ratio	1 : 3	3 : 1	1 : 1	1 : 1	10 : 1
HLA association	DR4	B27	B27 (axial)	B27 (axial)	B27
Joint pattern	Symmetrical, peripheral	Axial	Axial and peripheral	Axial and asymmetrical, peripheral	Axial and asymmetrical, peripheral
Sacroiliac	Absent	Symmetrical	Symmetrical	Asymmetrical	Asymmetrical
Syndesmophyte	Absent	Smooth, marginal	Smooth, marginal	Coarse, nonmarginal	Coarse, nonmarginal
Eye	Scleritis	Iritis	+/−	+/-	Iritis and conjunctivitis
Skin	Vasculitis	Rare	Erythema nodosum	Psoriasis	Keratoderma
Rheumatoid factor	>80%	Rare	Rare	Rare	Rare

HLA = human leukocyte antigen.

Peripheral oligoarthritis is seen in up to 30% of patients with ankylosing spondylitis. Typically, it is an asymmetrical oligoarthritis with a predilection for the lower extremities. It is important to ask about concurrent or previous tendinitis (e.g., Achilles tendinitis) or heel pain (e.g., plantar fasciitis), because either may reflect an enthesitis (Chapter 242) that is part of the clinical picture. Involvement of the hip can occur at any point in the course of ankylosing spondylitis and can progress to joint destruction. On standing and walking, a hip flexion contracture may contribute to an increasing stoop that might otherwise be attributed to spinal involvement in the disease.

Ocular involvement may occur in up to 40% of ankylosing spondylitis patients, most typically acute anterior uveitis (iritis). The uveitis often manifests as a slight impairment in visual acuity, with accompanying photophobia and eye pain. Typically, it is unilateral and recurrent. Inflammatory bowel disease (Chapter 127) and psoriasis (Chapter 405) occur in approximately 10% of patients with ankylosing spondylitis. Less common manifestations include aortic insufficiency (Chapter 60), cardiac conduction defects (Chapter 51), and apical pulmonary fibrosis (Chapter 80).

DIAGNOSIS

Physical Examination

Physical examination of the spine characteristically indicates restricted movement, which in the early stages may partly reflect paraspinal muscle spasm but later in the course reflects ankylosis of the zygapophyseal joints and syndesmophyte bridging of the vertebral bodies.[7] Changes in cervical mobility can be measured as the occiput-to-wall distance, with the patient's heels against the wall as the patient attempts to touch the back of the head to the wall. Thoracic involvement is measured in chest expansion, with the chest circumference at maximal inspiration being more than 5 cm greater than the circumference at maximal expiration. In the lumbar spine, forward flexion is restricted and can be monitored by the Schober test. This test is used to measure mobility in the lower part of the back: with the patient standing upright, a 10-cm span is marked from the fifth lumbar vertebra upward. On maximal forward flexion, the distance between the marks is remeasured. With normal spinal mobility, the flexed distance should register as 15 cm or an increment of 5 cm. Restricted spinal mobility early in the course of the disease may best be detected by lateral spinal flexion, measured as the difference in the finger-to-floor distance when standing erect compared with maximal bending to the side. Inflammation in the sacroiliac joint may be reflected by joint line tenderness to direct pressure or by the FABERE test (for Flexion, ABduction, External Rotation, and Extension) or Gaenslen maneuver. In the former, the patient lies supine while the examiner flexes and externally rotates the hip. In the latter, the examiner extends the hip by letting the leg dangle off the side of the examining table. In both cases, stress is placed on the sacroiliac joint and may reproduce the back pain if it derives from this site.

Laboratory Findings

Laboratory tests in the evaluation of inflammatory back pain are relatively nonspecific. The ESR and CRP are typically elevated, but normal levels do not exclude inflammatory back pain, and the degree of elevation is typically less than would be seen in active rheumatoid arthritis. Anemia of chronic disease may be observed if the condition is long-standing. HLA-B27 is rarely the definitive factor for diagnosis, but the test has reasonably high sensitivity and specificity in the setting of characteristic back symptoms.

Imaging

Radiographic assessment is important to confirm the diagnosis, but no radiographic changes may be seen in the sacroiliac joints early in the course of disease. If the clinician has a high index of suspicion, MRI may improve the sensitivity of the plain radiograph because inflammatory changes on MRI predate radiographic changes. A routine anteroposterior pelvic radiograph is generally the standard diagnostic radiograph, and the classic findings are bilateral changes in the sacroiliac joints (Fig. 244-2). Abnormalities include erosions in the joint line, pseudowidening, subchondral sclerosis, and, finally, ankylosis that reflects complete bony replacement of the sacroiliac joints.

Radiographs of the spine may reveal squaring of the vertebral bodies (loss of the normal anterior concavity of the lumbar vertebra) and "shiny corners" (subchondral sclerosis at the upper edge of the vertebral body), both of which are manifestations of enthesitis. Syndesmophytes, which represent marginal bridging of the vertebrae (Figs. 244-3 and 244-4), eventually develop and make the diagnosis clear. Because ankylosis of the apophyseal joints may occur without syndesmophyte formation, it is important to assess the posterior joints on lateral views of the lumbosacral spine, as well as the anterior margin of the vertebrae. Eventually, the changes may result in a "bamboo spine," so called because the bridging syndesmophytes can mimic the appearance of bamboo.

Differential Diagnosis

The differential diagnosis of ankylosing spondylitis includes osteitis condensans ilii; diffuse idiopathic skeletal hyperostosis (DISH; Chapter 238); the syndrome of synovitis, acne, pustulosis, hyperostosis, and osteomyelitis (SAPHO); and some induced hyperostotic states (e.g., vitamin A intoxication, fluorosis). New bone formation occurs in degenerative disc disease, but the bulky horizontal appearance of osteophytes is usually easily distinguished from that of syndesmophytes, and narrowing of the disc space is not a feature of ankylosing spondylitis. Osteoarthritis of the sacroiliac joint is more common than previously appreciated.

REACTIVE ARTHRITIS

DEFINITION AND EPIDEMIOLOGY

Reactive arthritis is an aseptic arthritis that occurs subsequent to an extra-articular infection, most typically of the gastrointestinal or genitourinary tract.[8] Typically, the onset of arthritis occurs 1 to 3 weeks after the gastrointestinal

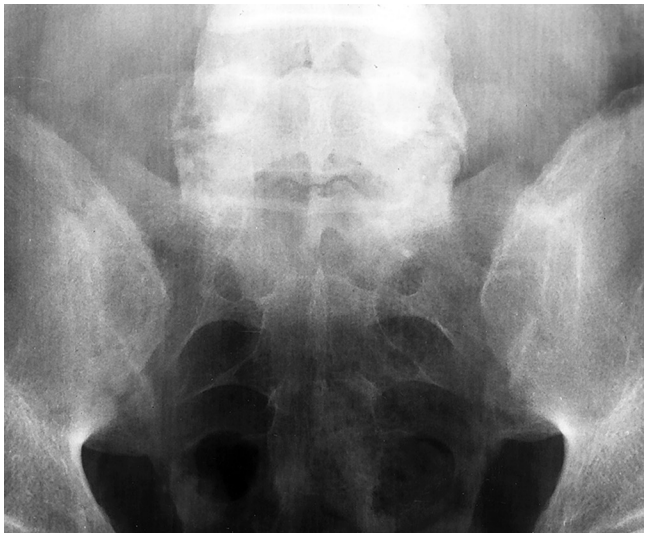

FIGURE 244-2. Bilaterally symmetrical sacroiliitis in ankylosing spondylitis.

FIGURE 244-5. Keratoderma blennorrhagicum of the feet in reactive arthritis.

or genitourinary infection, but the temporal details are often difficult to define precisely.

In the gastrointestinal tract, the key pathogens are *Salmonella typhimurium*, *Yersinia enterocolitica*, *Shigella flexneri*, and *Campylobacter jejuni*. In the genitourinary tract, *Chlamydia trachomatis* is the most common offender.

The true incidence and prevalence of reactive arthritis are not well defined. In epidemics involving *Salmonella* (Chapter 284) or *Yersinia* (Chapter 288), reactive arthritis develops in 2 to 7% of infected individuals but in as many as 20% of B27-positive infected individuals. In such epidemic studies, B27 confers risk not only for the onset of arthritis but also for axial involvement and chronicity. Genetic variants in toll-like receptor 2 (TLR-2) implicate host innate immunity as central in reactive arthritis.

PATHOBIOLOGY

Although immunofluorescence studies have identified bacterial antigens in the joints of patients with reactive arthritis after both gastrointestinal and genitourinary infections, results of polymerase chain reaction studies on synovial tissues have most consistently been positive in post-*Chlamydia* reactive arthritis, thereby suggesting that viable *Chlamydia* may persist in the joints of such patients, albeit in a metabolically altered state. Dactylitis is the net result of inflammatory changes affecting the joint capsule, entheses, periarticular structures, and periosteal bone.

Although the definition of aseptic arthritis after an extra-articular infection may include a broader range of pathogens (e.g., *Chlamydia pneumoniae*), sites of infection (e.g., streptococcal pharyngitis), and types of infections (e.g., *Giardia* infections of the GI tract), these clinical scenarios have not generally been included in the category of reactive arthritis. These postinfectious syndromes lack the other associated clinical features of spondyloarthritis and they lack an association with B27.

CLINICAL MANIFESTATIONS

The pattern of joint involvement in reactive arthritis is one of asymmetrical oligoarthritis with a predilection for the lower extremity, a pattern shared by most spondyloarthritis syndromes. Enthesitis may present as Achilles tendinitis or plantar fasciitis. Dactylitis, appearing as a sausage digit, may also be seen. Sacroiliitis may be seen in the acute phase, but radiographic changes are seen largely in patients with a more chronic course.

Reactive arthritis can be accompanied by extra-articular features such as urethritis, conjunctivitis, or mucocutaneous lesions. The urethritis may manifest as dysuria or discharge, and the rash as circinate balanitis, which appears as vesicles or shallow ulcerations on the glans penis. Painless lingual or oral ulcerations may also be seen. The fact that the cervicitis may be less symptomatic could partially account for the underdiagnosis in women. The classic skin manifestation of reactive arthritis is keratoderma blennorrhagicum, a painless papulosquamous eruption on the palms or soles (Fig. 244-5). Occasionally, nail dystrophy with pitting and onycholysis or subungual keratosis can be seen. The conjunctivitis can be bilateral and painful; in contrast, the acute anterior uveitis that can also be seen in this setting tends to be less painful and unilateral.

DIAGNOSIS

Radiographic changes of reactive arthritis can be seen in the involved peripheral joints, with early findings consisting of soft tissue swelling and juxta-articular osteopenia. Areas of periostitis and new bone formation may develop in peripheral joints. When changes in the sacroiliac joints are seen, they are typically asymmetrical (Fig. 244-6), in contrast to the symmetrical pattern seen in ankylosing spondylitis. In the chronic phase, syndesmophytes may develop, but they are bulky, nonmarginal, and often asymmetrical formations that differ from the classic syndesmophytes of ankylosing spondylitis. The frequency with which reactive arthritis evolves into bona fide ankylosing spondylitis has not been determined definitively.

The most important differential diagnosis for reactive arthropathies is septic arthritis (Chapter 251). Both *Yersinia* (Chapter 288) and *Salmonella* (Chapter 284) can cause septic arthritis, so an appropriate culture of synovial fluid should precede the diagnosis of reactive arthritis whenever possible.

REACTIVE ARTHRITIS AND HUMAN IMMUNODEFICIENCY VIRUS

An aggressive form of spondyloarthritis may be seen in patients who are concomitantly infected with HIV (Chapter 359). The frequency of reactive arthritis is not increased in patients with HIV, but HIV may alter the course of these arthropathies, with a tendency for a more aggressive and more refractory joint disease. Aggressive skin and joint disease may be seen in patients in whom psoriatic arthritis develops in the setting of HIV infection. Most North American patients with the HIV-reactive arthritis constellation are B27 positive, but studies of comparable patients in Africa have found a sizable B27-negative component in such patients. The arthritis in these patients falls into two clinical patterns: (1) an additive, asymmetrical polyarthritis or (2) an intermittent oligoarthritis that most commonly affects the lower extremities. Enthesitis, fasciitis, conjunctivitis, and urethritis can all be seen in such patients. Sacroiliitis can occur, although extensive spinal syndesmophyte formation is not common.

ENTEROPATHIC ARTHRITIS

EPIDEMIOLOGY

Enteropathic arthritis refers to the arthritis associated with Crohn disease or ulcerative colitis (Chapter 127; Table 244-4).[9] All extra-enteric manifestations, including arthritis, occur more commonly in Crohn disease than in ulcerative colitis. Peripheral arthritis occurs in 10 to 20% of patients with Crohn disease and in 2 to 7% of patients with ulcerative colitis. Axial disease occurs in 2 to

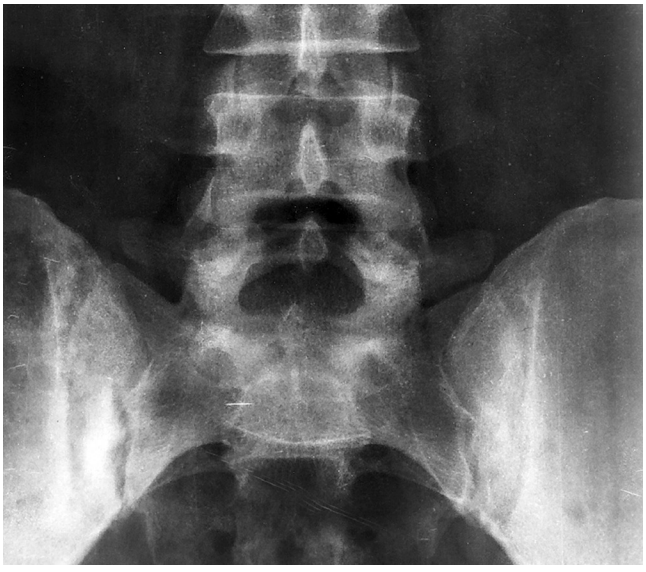

FIGURE 244-6. Bilaterally asymmetrical sacroiliitis in reactive arthritis. Erosions, pseudowidening, and ileal sclerosis are present.

TABLE 244-4 ENTEROPATHIC ARTHRITIS

FEATURE	PERIPHERAL ARTHRITIS	SACROILIITIS, SPONDYLITIS
CROHN DISEASE		
Frequency in Crohn disease	10-20%	2-7%
HLA-B27 associated	No	Yes
Pattern	Transient, symmetrical	Chronic
Course	Related to activity of Crohn disease	Unrelated to activity of Crohn disease
Effect of surgery	Remission of arthritis uncommon	No effect
Effect of anti-TNF therapy	Effective	Effective
ULCERATIVE COLITIS		
Frequency in ulcerative colitis	5-10%	2-7%
HLA-B27 associated	No	Yes
Pattern	Transient	Chronic
Course	More common in pancolitis than proctitis; related to activity of ulcerative colitis	Unrelated
Effect of surgery	Remission of arthritis	No effect

HLA = human leukocyte antigen; TNF = tumor necrosis factor.

7% of patients with either Crohn disease or ulcerative colitis. HLA-B27 is found in 50% of patients with axial arthritis.

PATHOBIOLOGY

The association of bowel inflammation and arthritis is supported by ileocolonoscopic studies in which subclinical inflammation of the bowel has been demonstrated in diseases covering the entire spectrum of spondyloarthritis. Histologic evaluation demonstrates that changes of acute ileitis are seen in postdysenteric reactive arthritis, whereas chronic inflammatory changes are more likely to be seen in patients with ankylosing spondylitis. Altered bowel permeability, with enhanced bacteremia or antigenemia, may provide the link in both cases.[10]

CLINICAL MANIFESTATIONS

Peripheral arthritis occurs more commonly in patients who have other extra-enteric features (e.g., erythema nodosum, iritis).[11] It is typically an inflammatory nonerosive polyarthritis, predominantly of large joints. In general, the clinical activity of the peripheral arthritis parallels the activity of the gut inflammation. The peripheral arthritis of enteropathic arthritis is not associated with B27. In contrast, the sacroiliitis or spondylitis of enteropathic arthritis follows a pattern in which the joint inflammation waxes and wanes independently of the bowel inflammation.

DIAGNOSIS

The musculoskeletal features of enteropathic arthritis may precede any gastrointestinal symptoms or signs. Conversely, the diarrhea preceding the onset of peripheral or axial arthritis in a young patient is just as likely to represent a food-borne pathogen (e.g., *Salmonella*, *Yersinia*) with secondary reactive arthritis as it is to represent inflammatory bowel disease with accompanying enteropathic arthritis. In the initial assessment of such a patient, it is important to perform careful and complete stool cultures. If the gastrointestinal symptoms persist, diagnostic colonoscopy is often required to resolve the diagnosis.

PSORIATIC ARTHRITIS

EPIDEMIOLOGY

One in four patients with psoriasis (Chapter 405) also has psoriatic arthritis.[12] Although most cases arise in patients with established cutaneous disease, some patients (particularly children) have arthritis that antedates the appearance of the skin lesions. Although the extent of psoriatic skin disease correlates poorly with the development of arthritis, the risk for psoriatic arthritis increases with a family history of psoriasis. The age at onset can range from 30 to 55 years, with an equal predilection for psoriatic arthritis in women and men. Psoriatic spondylitis has a slight male preponderance. Large prospective studies also suggest that obesity is a significant risk factor for psoriatic arthritis.

PATHOBIOLOGY

The genetic associations with psoriatic arthritis are complex. Psoriasis itself is associated with several HLA loci; some B alleles have been reported, but the dominant element is HLA-Cw6. HLA-B39 and HLA-B27 have been associated with sacroiliitis and axial involvement. No etiologic agent has been documented in psoriatic arthritis. The histopathology of the synovitis of psoriatic arthritis is comparable to that of the other forms of spondyloarthritis, with the absence of the local production of immunoglobulin and rheumatoid factor differentiating this disease from rheumatoid arthritis.[13]

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The two most common forms of psoriatic arthritis are asymmetrical oligoarthritis that usually involves both large and small joints and a symmetrical polyarthritis that mimics rheumatoid arthritis, except for the absence of rheumatoid factor.[14] A third subset of psoriatic arthritis has selective targeting of the distal interphalangeal joints. Arthritis is often associated with nail onycholysis, subungual keratosis, pitting, and oil drop–like staining (Fig. 244-7). The fourth clinical subset is psoriatic spondylitis, which usually occurs in conjunction with peripheral arthritis but can be the sole manifestation in 2 to 4% of patients with psoriatic arthritis.[15] Approximately 30 to 50% of patients with psoriatic arthritis are B27 positive. Finally, arthritis mutilans (less than 5% of patients) is a destructive, erosive arthritis that affects large and small joints and is usually associated with marked deformities and significant disability. Dactylitis, with sausage-like digits, can be seen in up to 40% to 50% of patients and is associated with more severe radiographic joint damage (Fig. 244-8).[16] Enthesitis occurs in 30 to 50% of patients with psoriatic arthritis, with the most common sites being the Achilles tendon and plantar fascia.

Radiology

Radiographic changes in psoriatic arthritis involve soft tissue swelling (particularly in the case of dactylitis), erosions, and periostitis. Axial involvement may lead to the appearance of asymmetrical sacroiliitis with syndesmophytes that are bulky, asymmetrical, and nonmarginal. The classic "pencil-in-cup" deformity may be seen in patients with distal interphalangeal joint disease or arthritis mutilans. Acro-osteolysis is noted in a minority of patients and reflects an aggressive erosive process.

Differential Diagnosis

The diagnosis of psoriatic arthritis depends on finding the typical skin or nail changes (Chapter 405) in association with one of the articular variants described previously. The differential diagnosis for the skin lesions can include seborrheic dermatitis, dyshidrotic eczema, fungal infection, keratoderma blennorrhagicum, and palmoplantar pustulosis.

FIGURE 244-7. Nail pitting in psoriasis. The pits are more discrete and regular compared with pits affecting the nail plate in dermatitis.

FIGURE 244-8. Dactylitis in psoriatic arthritis. Dactylitis in the first and second digits as seen in this patient with psoriatic arthritis is generally associated with more severe disease.

PERIPHERAL SPONDYLOARTHRITIS

Despite careful clinical and radiographic assessment, a substantial number of patients do not fall into one of the classic diagnostic subsets of spondyloarthritis. These patients are often defined as having peripheral spondyloarthritis with peripheral enthesitis, asymmetrical arthritis or sacroiliitis, or iritis in the absence of identifiable antecedent infection or concurrent inflammatory bowel disease or psoriasis.

TREATMENT

General Measures

Spondyloarthritis necessitates a global approach to management in which education of patients is the cornerstone. Because the typical onset is during young adulthood, patients may experience significant frustration or depression if their acute arthritis evolves into a chronic disease that significantly impairs their functional capabilities and quality of life. A clinician managing patients with spondyloarthritis should be aware that these psychosocial aspects are an important part of the burden of illness. Similarly, there may be important implications for the workplace, particularly if a job demands significant bending or twisting.

Exercise is an important part of the treatment plan for patients with ankylosing spondylitis. Generally, high-impact sports should be avoided, whereas water therapy and swimming are ideal. Stretching to maintain mobility and maintenance of posture should be emphasized, and an experienced physiotherapist can greatly assist in instructing patients in daily exercises. Long car trips and air travel should include periodic stretching. Sleep position should emphasize a straight back position rather than one curled on the side. Deep breathing exercises and avoidance of smoking should be stressed.

Medications

Nonsteroidal Anti-Inflammatory Drugs

In general, joint inflammation in spondyloarthritis improves significantly with the use of nonsteroidal anti-inflammatory drugs (NSAIDs; Table 26-4). Indomethacin and diclofenac (up to 150 mg/day in divided doses) or naproxen (up to 1000 mg/day in divided doses) are generally well tolerated in this population.[A1] These agents must be used with caution in enteropathic arthritis because of concern about exacerbating possible underlying inflammatory bowel disease. For patients with axial spondyloarthritis, the goal with anti-inflammatory treatment is to achieve sufficient relief of pain and stiffness to allow an active, sustained program of exercise and physical activity that maintains posture and improves quality of life.

Biologic Therapies

Biologic agents such as monoclonal antibodies to TNF-α (infliximab, 5 mg/kg IV at 0, 2, and 6 weeks, then every 8 weeks; adalimumab, 40 mg subcutaneously every 2 weeks; golimumab, 50 mg subcutaneously every 4 weeks; and certolizumab, 400 mg subcutaneously at 0, 2, and 4 weeks, then 200 mg every 2 weeks or 400 mg every 4 weeks) or the soluble TNF receptor (etanercept, 50 mg subcutaneously weekly) are effective for the treatment of spondyloarthritis.[A2] Other FDA-approved alternatives include the interleukin[IL]-17A inhibitors secukinumab (150 mg subcutaneously weekly for 5 weeks, then 150 mg subcutaneously every 4 weeks) and ixekizumab (80 mg subcutaneously every 2 or 4 weeks), each of which significantly reduces the signs of ankylosing spondylitis.[A3–A6] The oral Janus kinase inhibitors (upadacitinib, 15 mg daily, and tofacitinib, 5 mg orally twice weekly) are another promising potential option for axial spondyloarthritis.[A7,A8] These therapies result in a prompt improvement in clinical measures, in laboratory indicators of inflammation, and in MRI evaluations of the sacroiliac joints and spine.

These biologic agents have been well tolerated, with an acceptable side effect profile,[17,18] but patients appear to relapse when treatment is discontinued.[A9] For instance, in patients whose active nonradiographic axial spondyloarthritis goes into sustained remission with adalimumab, continued therapy reduces subsequent flares compared with withdrawing treatment.[A10] Experience with longer-term treatment with TNF and IL-17A inhibitors have been encouraging with regard to the persistence of the clinical therapeutic effect, the ability to retard radiographic progression, and the infrequency of late adverse events.

Corticosteroids

The response to the intra-articular injection of steroids in the peripheral joints of patients with spondyloarthritis is often neither as dramatic nor as sustained as in those with rheumatoid arthritis. Corticosteroid injection into the sacroiliac joints, usually performed under imaging guidance (fluoroscopy or computed tomography [CT]), can result in a good response in 80% of patients, with improvement persisting for many months. Topical steroids are usually effective for the treatment of the mucous membrane and skin manifestations of reactive arthritis and psoriasis. For uveitis (Chapter 391), topical corticosteroid eye drops are an integral component of management, and treatment should be monitored jointly with an ophthalmologist.[19] Systemic corticosteroids (either orally or via an intravenous bolus protocol) are not generally recommended but have been used for severe symptomatic flares, despite few controlled trials to validate their effectiveness. The goal should be prompt tapering of the dose when symptomatic control is achieved. The recognition that osteoporosis (Chapter 225) is a significant problem in axial spondyloarthritis provides further impetus to use corticosteroids sparingly.

Other Drugs

Sulfasalazine

In patients with ankylosing spondylitis, psoriatic arthritis, and reactive arthritis, sulfasalazine (2 g/day) improves peripheral arthritis but not axial diseases compared with placebo, mostly in patients with psoriatic arthritis. For ankylosing spondylitis, etanercept is superior to sulfasalazine with respect to symptomatic improvement as well as MRI evidence of inflammation.

Methotrexate

In patients with spondyloarthritis, methotrexate has shown benefit for peripheral joint disease but not for the spinal inflammation characteristic of ankylosing spondylitis. Methotrexate does not change the course of axial involvement in ankylosing spondylitis and has not provided robust long-term benefit.

Antibiotic Therapy

It is sound clinical practice to treat any culture-proven chlamydial urethritis (Chapter 294) in conjunction with treatment of the sexual partner. For this indication, a single 1-g dose of azithromycin is as effective as doxycycline 100 mg twice a day for 7 days. The role of antibiotics in the management of reactive arthritis has been controversial, but either rifampin (300 mg orally daily) plus azithromycin (500 mg orally daily for 5 days, then 500 mg weekly) or rifampin (300 mg orally daily) plus doxycycline (100 mg orally twice daily) therapy for 6 months may be useful for *Chlamydia*-induced reactive arthritis.

Approach to Specific Spondyloarthropathies

For each form of spondyloarthritis, consensus guidelines from the American College of Rheumatology/Spondylitis Association of America/Spondyloarthritis Research and Treatment Network can help guide medical therapy (Fig. 244-9).[20–22]

Psoriatic Arthritis

As a general approach, nonsteroidal anti-inflammatory drugs are recommended to relieve musculoskeletal signs and symptoms in psoriatic arthritis.[23] The presence of concomitant extra-articular features should be considered when selecting a therapeutic agent. Patients who have failed an advanced therapeutic agent can be switched to another agent in the same class or can switch to an agent with a different mechanism of action.

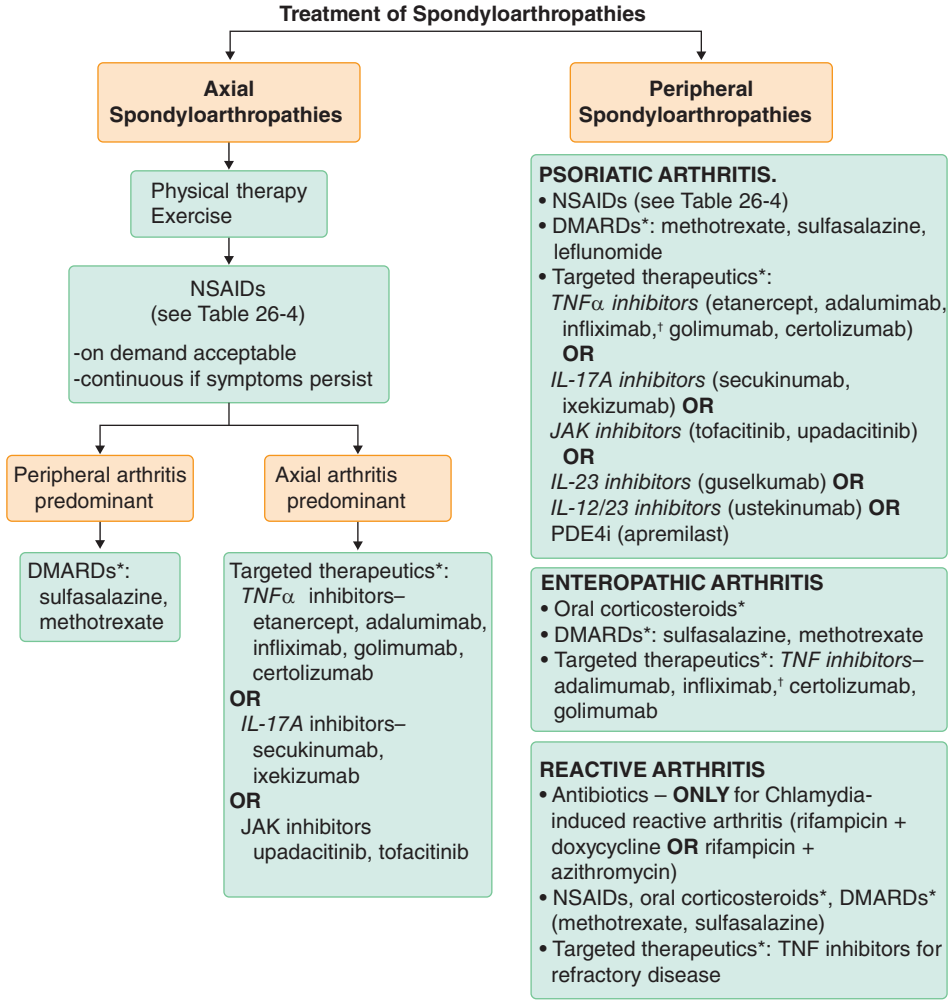

FIGURE 244-9. Treatment recommendations for the spondyloarthropathies. *See text for drug doses. †6 weeks for ankylosing spondylitis; 8 weeks for psoriatic arthritis. DMARDs = disease-modifying antirheumatic drugs; IL = interleukin; JAK = Janus kinase; NSAIDs = nonsteroidal anti-inflammatory drugs; TNF = tumor necrosis factor. (Adapted from Ward MM, Deodhar A, Gensler LS, et al. 2019 update of the American College of Rheumatology/Spondylitis Association of America/Spondyloarthritis Research and Treatment Network: recommendations for the treatment of ankylosing spondylitis and nonradiographic axial spondyloarthritis. *Arthritis Rheumatol*. 2019;71:1599-1613.)

Treatment with disease-modifying drugs (e.g., methotrexate, sulfasalazine, or leflunomide) is recommended in patients with swollen joints, structural damage in the presence of inflammation, or clinically relevant extra-articular manifestations. Tight control of inflammation using a treat-to-target approach significantly improves outcomes.[A11] Patients with mild psoriasis typically receive topical corticosteroids, whereas patients with moderate to severe psoriasis are treated with systemic therapies (Chapter 405). The anti-TNF agents, infliximab, etanercept, adalimumab, and golimumab are efficacious.[A12] Interleukin-17A monoclonal antibodies (secukinumab and ixekizumab) are also highly effective treatments for psoriatic arthritis.[A13,A14] The doses and frequency of administration for these biologics are generally similar to those used for axial spondyloarthritis. Other FDA-approved therapies include a monoclonal antibody against interleukin-12/23 (ustekinumab, 45 mg subcutaneously at 0 and 4 weeks, then every 3 months), oral Janus kinase inhibitors (tofacitinib, 5 mg twice daily, and upadacitinib, 15 mg once daily),[A15,A16] and a monoclonal antibody against the P19 subunit of interleukin-23 (guselkumab, 100 mg subcutaneously at 0 and 4 weeks, and then every 8 weeks).[A17,A18] These therapies inhibit the progression of structural damage, with continued clinical efficacy and acceptable safety. Apremilast is an oral phosphodiesterase-4 inhibitor (30 mg orally twice daily) that improves only signs and symptoms of psoriatic arthritis and with less benefit than with the biologic agents.

Reactive Arthritis

The treatment of reactive arthritis begins with therapy of the triggering infection. For example, in patients who are PCR-positive either in blood or joint fluid for *C. trachomatis* or *C. pneumonia*, a 6-month course of combination therapy with rifampicin (300 mg/day) plus either doxycycline (100 mg twice daily) or azithromycin (500 mg twice daily for 5 days followed by 500 mg once a week) yields a response in 65% of patients (compared with about 20% with placebo), and complete remission is observed in 20% (compared with 0% with placebo). For reactive arthritis, NSAIDs and glucocorticoid injections are effective. In more severe cases, sulfasalazine is often effective if started in the first 3 months.

Biologic therapies are often used in chronic HLA-B27 positive spondyloarthritis, although their efficacy is unproven, especially since about 50% of patients recover within about 6 months.

Enteropathic Arthritis

For enteropathic arthritis, sulfasalazine is more helpful in ulcerative colitis than in Crohn disease (Chapter 127), whereas the opposite is generally true for methotrexate. TNF-α inhibitors (see Fig. 244-9) are effective in spondyloarthritis related to both ulcerative colitis and Crohn disease. A multidisciplinary approach can improve the management of rheumatic disease in patients with inflammatory bowel disease, thereby allowing more comprehensive care.

PROGNOSIS

Patients are typically concerned about their prognosis, because spondyloarthritis often occurs in young, active individuals for whom physical activity is a priority.

Ankylosing Spondylitis

The clinical course and severity of ankylosing spondylitis are highly variable. Inflammatory back pain and stiffness dominate the picture in the early stages, whereas chronic pain and deformity may develop over time. In both its early and late phases, the disease may have a significant impact on work disability and quality of life. The strongest predictor of new syndesmophyte formation is the presence of syndesmophytes at baseline. In ankylosing spondylitis patients in whom new, refractory spinal pain develops, an intervertebral fracture can occur after only minimal trauma.

Osteoporosis (Chapter 225) is a significant consequence of ankylosing spondylitis, probably reflecting both the local chronic inflammation and the

abnormal biomechanical loading of the vertebrae as the disease progresses. Additional late complications may include cauda equina syndrome, osteoporotic compression fractures, spondylodiscitis, and restrictive lung disease.

Reactive Arthritis

The course of reactive arthritis is variable, and few prognostic markers are available for the clinician to predict the course in an individual case. However, the majority of patients have an initial episode lasting 2 to 3 months, but synovitis may persist for a year or longer. In one follow-up of a point source cohort of post-*Salmonella* reactive arthritis, 20% of patients had ongoing inflammatory joint disease, and some degree of functional disability was observed in 30% of patients 5 years after the onset of disease.

Enteropathic Arthritis

For peripheral arthritis, measures that control the gastrointestinal disease usually control the joint disease as well. In contrast, the course of enteropathic spondylitis or sacroiliitis tends to be chronic.

Psoriatic Arthritis

Aggressive osteolysis, fibrous ankylosis, and heterotopic new bone formation can occur in psoriatic arthritis. The coexistence of HIV and psoriatic arthritis seems to set the stage for an aggressive course of joint destruction in some patients. Patients with psoriatic arthritis can experience substantial physical impairment.[24]

Peripheral Spondyloarthritis

The natural history of peripheral spondyloarthritis has not been well defined. A number of patients may eventually meet the diagnostic criteria for axial spondyloarthritis, but many retain a distinct undifferentiated spondyloarthritis pattern for prolonged periods. The variability in prognosis for the large group of patients falling into the peripheral spondyloarthritis group is perplexing. No characteristics are reliable predictors of progression in patients with this heterogeneous cluster of articular and extra-articular features.

245 SYSTEMIC LUPUS ERYTHEMATOSUS

MARY K. CROW

DEFINITION

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease that results from immune system–mediated tissue damage. The molecular triggers of the disease are not known, but the pathogenesis involves the production of autoantibodies specific for nucleic acids and nucleic acid–binding proteins. Immune complexes, along with immune system cells and soluble mediators, generate inflammation and tissue damage. Manifestations of SLE can involve the skin, joints, kidney, central nervous system (CNS), cardiovascular system, serosal membranes, and hematologic and immune systems. The disease is highly heterogeneous, with individual patients manifesting variable combinations of clinical features. In most patients with SLE, the disease is characterized by a waxing and waning clinical course, although some patients demonstrate a pattern of chronic activity. Therapeutic approaches generally involve immunosuppression, although promising biologic agents targeting specific molecular mechanisms are in development.

EPIDEMIOLOGY

A notable feature of SLE is that it occurs much more frequently in females than in males. As in Hashimoto thyroiditis and Sjögren syndrome, the female-to-male ratio is approximately 9 : 1 in adults, and most cases are diagnosed between the ages of 15 and 44 years. In children and patients older than age 55 years, the ratio is closer to 2 : 1. The prevalence of SLE in the United States is estimated to be approximately 72.8 per 100,000, and the incidence of new cases is about 5.1 per 100,000 per year.[1,2] The prevalence, severity, and characteristics of disease differ in different ethnic groups, with SLE being three- to four-fold more prevalent in Black, American Indian, and Native Alaskan women than in White women. Asians also have a higher incidence of disease than Whites. The severity of disease, based on standardized mortality ratios, is greatest among Asians and Hispanics, although the highest percent mortality is among Blacks.[3] Studies of lupus in minority populations indicate that socioeconomic factors are major contributors to the increased prevalence and severity of disease in Blacks and Hispanic Americans.

PATHOBIOLOGY

Current understanding of lupus pathogenesis incorporates roles for genetic susceptibility based on a cumulative hit model involving multiple genes, environmental triggers (e.g., the endogenous microbiome or virome, microbial infection, sunlight), certain drugs,[4] and altered immune system function.[5] Studies of immunology, genetics, and epigenetics have focused attention on the mechanisms of nucleic acid sensing and the type I interferon pathway.[6] Impaired inactivation of the X-chromosome may partially explain the striking female sex predominance.[7] Induction of cellular stress responses, including oxidative modification of cell proteins, may link environmental triggers to altered immune function. Together, these mechanisms result in the generation

abnormal biomechanical loading of the vertebrae as the disease progresses. Additional late complications may include cauda equina syndrome, osteoporotic compression fractures, spondylodiscitis, and restrictive lung disease.

Reactive Arthritis

The course of reactive arthritis is variable, and few prognostic markers are available for the clinician to predict the course in an individual case. However, the majority of patients have an initial episode lasting 2 to 3 months, but synovitis may persist for a year or longer. In one follow-up of a point source cohort of post-*Salmonella* reactive arthritis, 20% of patients had ongoing inflammatory joint disease, and some degree of functional disability was observed in 30% of patients 5 years after the onset of disease.

Enteropathic Arthritis

For peripheral arthritis, measures that control the gastrointestinal disease usually control the joint disease as well. In contrast, the course of enteropathic spondylitis or sacroiliitis tends to be chronic.

Psoriatic Arthritis

Aggressive osteolysis, fibrous ankylosis, and heterotopic new bone formation can occur in psoriatic arthritis. The coexistence of HIV and psoriatic arthritis seems to set the stage for an aggressive course of joint destruction in some patients. Patients with psoriatic arthritis can experience substantial physical impairment.[24]

Peripheral Spondyloarthritis

The natural history of peripheral spondyloarthritis has not been well defined. A number of patients may eventually meet the diagnostic criteria for axial spondyloarthritis, but many retain a distinct undifferentiated spondyloarthritis pattern for prolonged periods. The variability in prognosis for the large group of patients falling into the peripheral spondyloarthritis group is perplexing. No characteristics are reliable predictors of progression in patients with this heterogeneous cluster of articular and extra-articular features.

245 SYSTEMIC LUPUS ERYTHEMATOSUS

MARY K. CROW

DEFINITION

Systemic lupus erythematosus (SLE) is a multisystem autoimmune disease that results from immune system–mediated tissue damage. The molecular triggers of the disease are not known, but the pathogenesis involves the production of autoantibodies specific for nucleic acids and nucleic acid–binding proteins. Immune complexes, along with immune system cells and soluble mediators, generate inflammation and tissue damage. Manifestations of SLE can involve the skin, joints, kidney, central nervous system (CNS), cardiovascular system, serosal membranes, and hematologic and immune systems. The disease is highly heterogeneous, with individual patients manifesting variable combinations of clinical features. In most patients with SLE, the disease is characterized by a waxing and waning clinical course, although some patients demonstrate a pattern of chronic activity. Therapeutic approaches generally involve immunosuppression, although promising biologic agents targeting specific molecular mechanisms are in development.

EPIDEMIOLOGY

A notable feature of SLE is that it occurs much more frequently in females than in males. As in Hashimoto thyroiditis and Sjögren syndrome, the female-to-male ratio is approximately 9 : 1 in adults, and most cases are diagnosed between the ages of 15 and 44 years. In children and patients older than age 55 years, the ratio is closer to 2 : 1. The prevalence of SLE in the United States is estimated to be approximately 72.8 per 100,000, and the incidence of new cases is about 5.1 per 100,000 per year.[1,2] The prevalence, severity, and characteristics of disease differ in different ethnic groups, with SLE being three- to four-fold more prevalent in Black, American Indian, and Native Alaskan women than in White women. Asians also have a higher incidence of disease than Whites. The severity of disease, based on standardized mortality ratios, is greatest among Asians and Hispanics, although the highest percent mortality is among Blacks.[3] Studies of lupus in minority populations indicate that socioeconomic factors are major contributors to the increased prevalence and severity of disease in Blacks and Hispanic Americans.

PATHOBIOLOGY

Current understanding of lupus pathogenesis incorporates roles for genetic susceptibility based on a cumulative hit model involving multiple genes, environmental triggers (e.g., the endogenous microbiome or virome, microbial infection, sunlight), certain drugs,[4] and altered immune system function.[5] Studies of immunology, genetics, and epigenetics have focused attention on the mechanisms of nucleic acid sensing and the type I interferon pathway.[6] Impaired inactivation of the X-chromosome may partially explain the striking female sex predominance.[7] Induction of cellular stress responses, including oxidative modification of cell proteins, may link environmental triggers to altered immune function. Together, these mechanisms result in the generation

ABSTRACT

Systemic lupus erythematosus (SLE) is a highly complex systemic autoimmune disease that involves nearly all components of the immune system and is associated with damage to multiple organs. SLE is notable for its female predominance, with about 8 to 10 females for every 1 male affected. The disease is characterized by autoimmunity specific for nucleic acids and nucleic acid–binding proteins. Current concepts in disease pathogenesis involve nucleic acid–mediated activation of the innate immune system, production of cytokines such as type I interferon, extensive immune system dysregulation, and production of autoantibodies that form immune complexes. Therapy typically depends on immunosuppression with corticosteroids, biologics, and other agents. Current studies are investigating the potential for novel agents to provide improved efficacy over current treatment options.

and deposition of immune complexes in tissue, the recruitment of lymphocytes, macrophages, and neutrophils, the activation of the complement system, and tissue damage.

Genetics

An important role for a genetic contribution to lupus susceptibility is suggested by the high concordance of disease in monozygotic twins (24%), with an estimated 44% of risk for SLE attributable to heritable factors. Rare mutations in genes encoding components of the complement pathway, including C1q, C2, and C4A, contribute to increased lupus susceptibility or severity. Impaired production of these early complement components may decrease the clearance of apoptotic or necrotic debris, thereby augmenting the pool of available autoantigens, or decrease the solubility of immune complexes. Rare mutations in genes encoding DNase enzymes can contribute to impaired degradation of endogenous DNA and induction of type I interferon. The association of SLE with the major histocompatibility complex (MHC) class II alleles human leukocyte antigen (HLA)-DR3 (DRB1*03:01-DQA1*05:01-DQB1*02:01) and HLA-DR15 (DRB1*15:01/03-DQA1*01:02-DQB1*06:01) shows the strongest risk, and these class II alleles are associated with the production of particular autoantibodies.[8] A large transancestral genome-wide association study (GWAS) of subjects of European, African, and Hispanic Amerindian ancestry identified 80 non-HLA single-nucleotide polymorphisms associated with SLE. Some associations at a high level of significance were related to ancestry (E-Table 245-1). Polymorphic variants in components of the toll-like receptor (TLR) pathways that regulate type I interferon production, including interferon regulatory factor 5 (*IRF5*) and *IRF7*, are associated with a diagnosis of SLE and increased plasma interferon activity in some populations. Polymorphisms in the Fc receptor genes *FCGR2A* and *FCGR3A* have been associated with SLE nephritis, possibly based on altered clearance of immune complexes. Variants of the *PTPN22* gene, which encodes a phosphatase that regulates T-cell activation, are also associated with SLE. GWASs have identified variations in regulators of innate immune system activation (e.g., *TNFAIP3, ITGAM, IFIH1*) and signaling molecules important in lymphocyte activation (e.g., *STAT4, BANK1*, and *BLK*). Rare mutations in genes encoding proteins that regulate nucleic acid integrity and degradation, including *TREX1*, encoding a DNase; *SAMHD1*, a triphosphohydrolase; *RNASEH2A, B*, and *C*; and *ADAR*, an RNA-specific adenosine deaminase, have been documented in some patients with a lupus-like disorder called Aicardi-Goutières syndrome, characterized by skin lesions, CNS disease, autoantibodies, and high levels of interferon. Mutations in these genes have also been documented in rare patients with SLE and highlight the likely contribution of endogenous nucleic acids to activation of the innate immune system and the pathogenesis of lupus. Composite genetic risk scores are associated with early onset of disease, tissue damage, and decreased survival.[9] These genetic loci that are associated with lupus confer either increased activation or impaired regulation of innate or adaptive immune responses (Chapter 35), with increased type I interferon often observed in association with the risk genotype.

Environmental Triggers

Epidemiologic studies have identified several classes of potential environmental triggers for lupus, including exposure to silica, smoking, and use of oral contraceptive agents or postmenopausal hormones. A role for microbial triggers—particularly virus infection—has been postulated, consistent with the constitutional symptoms that often characterize the earliest stage of the disease. Prior infection with Epstein-Barr virus (Chapter 348) is significantly higher in SLE patients than in the general population (99 vs. 94%). Orthologs of human Ro60, a common target of lupus autoantibodies, are seen in commensal bacteria.[10] Ultraviolet light exposure is a well-described trigger of lupus flares. Possible mechanisms include DNA damage, induction of cellular stress responses, and induction of apoptosis of skin cells, which result in concentration of nucleic acids and associated proteins in cell membrane blebs that can be processed by antigen-presenting cells. Certain drugs, including procainamide and hydralazine, can induce a lupus-like syndrome, but the symptoms usually abate after discontinuing use of the drug. These agents may promote demethylation of DNA, thereby altering gene expression and potentially increasing the availability of immunostimulatory DNA. Sulfa antibiotics have induced lupus flares in some patients. Administration of recombinant interferon-α to patients with hematologic malignancies or hepatitis C infection has been associated with induction of a lupus-like syndrome. In addition, anti–tumor necrosis factor agents have induced lupus autoantibodies and occasionally clinical lupus in patients with rheumatoid arthritis.

Immunologic Triggers

Genetic and environmental factors that increase the probability of development of SLE act on the immune system to induce autoimmunity and consequent tissue inflammation and damage. In addition to mechanisms that increase the availability of self-antigens (such as ultraviolet light), altered expression of gene products that mediate or regulate apoptosis or impaired clearance of apoptotic debris results in generalized activation of the immune system and contributes to autoimmunity in lupus. In parallel with the events that account for effective immune responses directed at exogenous microbes, the autoimmunity that occurs in SLE patients requires activation of both innate and adaptive immune responses (Chapter 35). Characterization of the TLR family of pattern recognition receptors has provided new understanding of the mechanisms through which the innate immune system is activated by exogenous and endogenous stimuli, including nucleic acid–containing immune complexes, and promotes induction of a self-directed adaptive immune response (Chapter 35). Impaired inactivation of the X-chromosome may augment the differentiation of B cells and the production of autoantibodies by increasing the expression of TLR7 or other X-chromosome–encoded immune response genes.

Type I Interferon

Studies of gene expression in peripheral blood mononuclear cells of SLE patients using microarray and RNA sequencing technology have demonstrated a sustained and broad "signature" of type I interferon–induced gene transcripts that reflect activation of the innate immune system. Interferon-α (IFN-α), along with other type I IFNs (e.g., IFN-β, IFN-ω, and IFN-κ in skin) may be responsible for many of the immunologic alterations observed in SLE. Immune complexes containing DNA or RNA, nuclear debris from neutrophils in the form of neutrophil extracellular traps (NETs), or extracellular mitochondrial DNA are among the stimuli postulated to induce the production of type I interferon in SLE. Demethylated CpG-rich DNA or RNA associated with nucleic acid–binding proteins can activate plasmacytoid dendritic cells and other immune system cells through TLRs and thereby result in the production of type I interferon and other proinflammatory cytokines (E-Fig. 245-1).[11] Induction of an immunostimulatory microenvironment by IFN-α may support the development of a humoral immune response directed at self-antigens, particularly intracellular particles that contain nucleic acids and nucleic acid–binding proteins. In addition to its effects on immune system function, type I interferon has been associated with altered endothelial cell function and microglial function in the brain and may contribute to the development of atherosclerotic vascular pathology and CNS disease in patients with lupus.[12]

Autoantibodies

The most characteristic lupus autoantibodies target intracellular particles that contain both nucleic acid and nucleic acid–binding proteins. Analysis of the spectrum of autoantibodies present in the sera of individuals in whom SLE is later diagnosed suggests that autoantibodies reactive with certain RNA-binding proteins, including the Ro protein, occur early in the preclinical stage of the disease, along with a positive antinuclear antibody (ANA) test. These abnormal test results are often followed by anti-double-stranded DNA antibodies and, finally, by the development of antibodies specific for the spliceosomal proteins Smith (Sm) and ribonucleoprotein (RNP) at approximately the time of diagnosis (E-Fig. 245-2). These observations suggest that individuals who demonstrate progression from antibodies targeting RNA to antibodies targeting DNA and spliceosomal proteins are those in whom sufficient autoimmunity develops to manifest clinical symptoms. Approximately one third of SLE patients have autoantibodies that are reactive with phospholipids or the proteins associated with them, particularly β_2-glycoprotein I. These autoantibody specificities can also be present independently of SLE in primary antiphospholipid antibody syndrome (Chapter 157).

Immune Complexes and Complement

Tissue and organ damage in SLE is mediated by the deposition or in situ formation of immune complexes, the activation of complement, and inflammation. The complement system (Chapter 37), which is composed of more than 30 proteins that act in concert to protect the host against invading organisms, initiates inflammation and tissue injury. Activation of complement promotes chemotaxis of inflammatory cells and generates proteolytic fragments that enhance phagocytosis by neutrophils and monocytes. The classical complement pathway is activated when antibodies bind to antigen and generate potent effectors. Activation of the alternative complement pathway is initiated by the binding of spontaneously activated complement components to the surfaces

E-TABLE 245-1 NON-HLA GENOMIC REGIONS ASSOCIATED WITH SYSTEMIC LUPUS ERYTHEMATOSUS BY ANCESTRY

GENE*	PROTEIN
EUROPEAN	
ATG5	Autophagy related 5
BANK1	B-cell scaffold protein with ankyrin repeats 1
BLK	B-lymphocyte–specific tyrosine kinase
CLEC16A	C-type lectin domain containing 16A
DEF6	DEF6, guanine nucleotide exchange factor
DGKQ	Diacylglycerol kinase theta
ETS1	ETS proto-oncogene 1
FCGR2A	Fc fragment of IgG receptor IIa
GRB2	Growth factor receptor bound protein 2
GTF2I	General transcription factor IIi
IFIH1	Interferon induced with helicase C domain 1
IKZF1	IKAROS family zinc finger 1
IKZF3	IKAROS family zinc finger 3
IL10	Interleukin 10
IL12A	Interleukin 12A
IRF5	Interferon regulatory factor 5
IRF7	Interferon regulatory factor 7
IRF8	Interferon regulatory factor 8
ITGAM	Integrin subunit alpha M
JAZF1	JAZF zinc finger 1
MSRA	Methionine sulfoxide reductase A
NMNAT2	Nicotinamide nucleotide adenylyltransferase 2
OLIG3	Oligodendrocyte transcription factor 3
PKIA	cAMP-dependent protein kinase inhibitor α
PTPN22	Protein tyrosine phosphatase nonreceptor type 22
PTTG1-MIR146A	Pituitary tumor–transforming 1
PXK	PX domain containing serine/threonine kinase–like
SLC15A4	Solute carrier family 15 member 4
SLC17A4	Solute carrier family 17 member 4
STAT4	Signal transducer and activator of transcription 4
TMEM39A	Transmembrane protein 39A-translocase of inner mitochondrial membrane
TIMMDC1	Mitochondrial membrane domain containing 1
TNFAIP3	TNF α-induced protein 3/A20
TNFSF4	TNF superfamily member 4/Ox40 ligand
TNIP1	TNFAIP3 interacting protein 1
TYK2	Tyrosine kinase 2
UBE2L3	Ubiquitin conjugating enzyme E2 L3
WDFY4	WDFY family member 4
AFRICAN	
BLK	B-lymphocyte–specific tyrosine kinase
IRF5	Interferon regulatory factor 5
ITGAM	Integrin subunit α M
PLAT	Plasminogen activator, tissue type
PTTG1	Pituitary tumor–transforming 1
HISPANIC	
CLEC16A	C-type lectin domain containing 16A
GALC	Galactosylceramidase
IRF5	Interferon regulatory factor 5
ITGAM	Integrin subunit alpha M
NCF2	Neutrophil cytosolic factor 2
TNIP1	TNFAIP3 interacting protein 1
STAT4	Signal transducer and activator of transcription 4

*Genes listed have *P* value $<5 \times 10^{-8}$.

cAMP = cyclic adenosine monophosphate; ETS = erythroblast transformation specific; HLA = human leukocyte antigen; IgG = immunoglobulin G; JAZF = juxtaposed with another zinc finger protein; PX = phox homology; TNF = tumor necrosis factor; TNFAIP3 = tumor necrosis factor, alpha-induced protein 3.

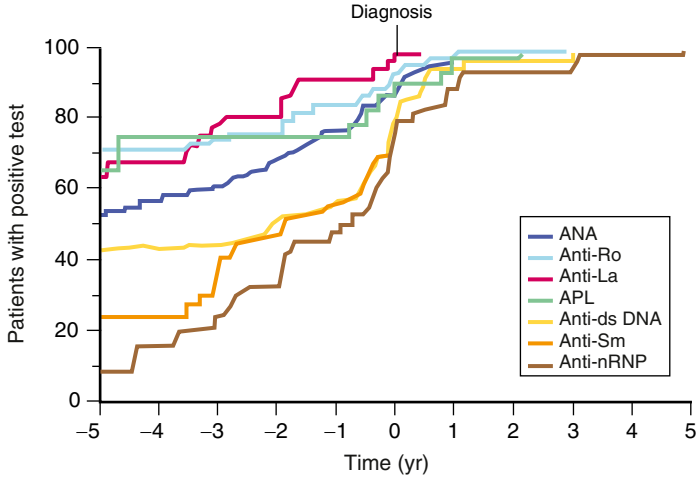
E-FIGURE 245-1. Model for induction of innate immune system activation in systemic lupus erythematosus. Both exogenous and endogenous stimuli can induce toll-like receptor (TLR) and cytosolic nucleic acid sensor activation and thereby result in new gene transcription. Among potential endogenous ligands are immune complexes containing DNA or RNA or matrix-derived components and cytosolic DNA or RNA. TLR ligands trigger the activation of intracellular adaptors, including TIR domain-containing adapter-inducing interferon-β (TRIF), TRIF-related adaptor molecule (TRAM), TIR domain-containing adapter protein (TIRAP), or myeloid differentiation primary response protein 88 (MyD88), and induce transcription of type I interferons or inflammatory cytokines. Cytosolic RNA activates RIG-I or MDA5, which signals through MAVS and TBK1. Cytosolic DNA activates cGAS, which signals through cGAMP, STING, and TBK1. Both pathways can induce type I interferon transcription. Type I interferons mediate diverse effects on immune system cells, including maturation of dendritic cells, increased immunoglobulin (Ig) class switching, and induction of cytokines that promote autoimmunity and inflammation, including B-lymphocyte stimulator (BLyS), interleukin-10 (IL-10), interferon-γ, and chemokines. AIM2 = absent in melanoma 2; ATP = adenosine triphosphate; cGAS = cyclic GMP-AMP synthase; ds = double-stranded; ER = endoplasmic reticulum; GTP = guanosine triphosphate; IFN = interferon; IRF = interferon regulatory factors; IRAK = interleukin-1 receptor-associated kinases; MDA5= melanoma differentiation-associated protein 5; NF-KB = nuclear factor-kappaB; RIG1 = retinoic acid-inducible gene 1; ss = single-stranded; STING = stimulator of interferon genes. (From Junt T, Barchet W. Translating nucleic acid-sensing pathways into therapies. *Nat Rev Immunol*. 2015;15:529-44.)



E-FIGURE 245-2. Proportion of patients with positive antibody tests relative to the time of diagnosis or appearance of the first clinical manifestation of systemic lupus erythematosus (SLE). For each autoantibody, the proportion of patients testing positive relative to the time of diagnosis or to the time of appearance of the first clinical criterion was assessed. In analyses of the time from antibody development to the diagnosis of SLE, antinuclear antibodies (ANAs) appeared significantly earlier than anti-Sm antibodies and antinuclear ribonucleoprotein (anti-nRNP) antibodies but not significantly earlier than anti-Ro, anti-La, antiphospholipid (APL), or anti-double-stranded DNA antibodies (anti-ds DNA). (From Arbuckle MR, McClain MT, Rubertone MV, et al. Development of autoantibodies before the clinical onset of systemic lupus erythematosus. *N Engl J Med*. 2003;349:16.)

of pathogens or self-tissues. C3a, which is an anaphylatoxin that binds to receptors on leukocytes and other cells, causes activation and release of inflammatory mediators. C5a is a potent soluble inflammatory, anaphylatoxic, and chemotactic molecule that promotes recruitment and activation of neutrophils and monocytes and mediates endothelial cell activation through its receptor. The release of reactive oxygen and nitrogen intermediates is an additional mechanism that contributes to tissue damage.

Tissues targeted by immune system activity in lupus include the skin (where immune complexes and complement are deposited in a linear pattern), the glomeruli, and heart valves. Antibodies reactive with hippocampal neurons in the brain can mediate excitotoxic death. Microvascular damage is observed in splenic arteries and is characterized by the typical onion-skin pattern of concentric connective tissue deposition. In addition to inflammation, thrombosis (including microthrombi) contributes to ischemia and cell necrosis in the brain and other organs.

Lupus Nephritis

In general, the pattern of renal disease reflects the site of deposition of immunoglobulins and the quality of the effector mechanisms they induce. Mesangial deposition of immunoglobulin induces mesangial cell proliferation and is associated with microscopic hematuria and mild proteinuria. Subendothelial deposition of immune complexes results in proliferative and exudative inflammation, together with hematuria, mild to moderate proteinuria, and reduced glomerular filtration rate. Subepithelial deposition of immune complexes adjacent to podocytes and along the glomerular basement membrane can result in membranous nephritis with nephrotic-range proteinuria. In addition, antiphospholipid antibodies may support the development of thrombotic or inflammatory vascular lesions within or external to glomeruli.

Neuropsychiatric Lupus

The pathophysiologic mechanisms that account for the neuropsychiatric manifestations of SLE are diverse and complex. Autoantibodies cross-reactive with neuronal cell surface glutamate receptors and DNA may mediate excitotoxic death of neurons and are proposed to contribute to cognitive dysfunction. Antibodies directed against ribosomal P protein have also been associated with neuropsychiatric lupus, and antiphospholipid antibodies can contribute to a procoagulant state, vascular thrombosis, and cerebral ischemia. Noninflammatory small vessel vasculopathy is the most common lesion and can be associated with microinfarcts. Inflammatory mediators, including the cytokines interleukin-6 (IL-6) and IFN-α, and matrix metalloproteinases may also contribute to the neuropsychiatric manifestations of SLE. IFN-α mediates microglial activation and excessive synaptic pruning.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Constitutional Symptoms

SLE involves virtually all components of the immune system and can be accompanied by constitutional symptoms similar to those seen in the setting of microbial infection. Fatigue, headaches, weight loss, and fevers are common, along with generalized arthralgias, myalgias, and lymphadenopathy. The level of activity of lupus typically follows a pattern of flares and remissions, although some patients sustain active disease for prolonged periods.

Cutaneous and Mucous Membranes

The skin and mucous membranes are affected in most lupus patients (Table 245-1). The classic erythematous facial rash, with a butterfly distribution across the malar and nasal prominences and sparing of the nasolabial folds, is seen in 30 to 60% of patients (Fig. 245-1). The butterfly rash is often triggered by sun exposure, but photosensitivity can also occur diffusely in other areas of the body.

Discoid skin lesions, which are seen in about 25% of patients, are erythematous plaques with central scarring, sometimes covered with scale and involving the scalp, face, and ears. Patients may develop alopecia (Chapter 409). Discoid lesions can be present in the absence of systemic manifestations of SLE (discoid lupus). In addition to the scarring alopecia of discoid lupus, transient alopecia may be a clinical sign of increased disease activity.

Inflammation of the deep dermis and subcutaneous fat can result in lupus panniculitis, with firm, painful nodules that sometimes adhere to the epidermis, thereby causing irregularities in the superficial skin. Subacute cutaneous lupus erythematosus is seen in sun-exposed areas and can involve erythematous plaques or psoriasiform lesions. It is associated with autoantibodies to the Ro (SSA) RNA-binding protein. Mucosal ulcerations, especially of the buccal mucosa and upper palate, result from mucositis and are typical of SLE. Manifestations of vasculopathy include arteriolar spasm or infarcts in the nail folds, a diffuse lacey pattern over the skin described as livedo reticularis, and petechial-purpuric or urticarial lesions on the extremities. Vasculopathy in SLE is often associated with the presence of antiphospholipid antibodies.

Musculoskeletal System

Arthralgias and nonerosive arthritis are experienced by more than 85% of patients. The proximal interphalangeal and metacarpophalangeal joints of the hand are most commonly symptomatic, along with the knees and wrists. In about 10% of patients, deformities result from damage to periarticular tissue, a condition termed *Jaccoud arthropathy*. The heavy use of corticosteroids in many lupus patients can be accompanied by the development of osteoporosis, including osteoporotic fractures, or osteonecrosis, most commonly of the hips, although the underlying vasculopathy can also contribute to joint damage.

Inflammation of the muscles with elevated creatine kinase levels can occur rarely in SLE, and myopathy may be observed as a consequence of corticosteroid therapy. Fibromyalgia (Chapter 253), characterized by painful trigger points at characteristic locations, commonly accompanies SLE and can contribute to fatigue and depression.

Renal System

Kidney involvement with glomerulonephritis (Chapter 107) is common in SLE, with more than 50% of patients affected at some time in the course of disease.[13] Patients may initially be asymptomatic, but hypertension is common, and the nephrotic syndrome can develop. Patients often develop progressive chronic kidney disease (Chapter 116). Renal vein thrombosis (Chapter 110) also can occur.

Cardiovascular System

Pericarditis (Chapter 62) is the most common cardiac manifestation,[14] but it is sometimes recognized only on imaging studies or at autopsy. Pericarditis is usually manifested as substernal chest pain that is improved by bending forward and can be exacerbated by inspiration or coughing.

Structural valve abnormalities in SLE range from sterile nodules (Libman-Sacks endocarditis) to nonspecific valve thickening. The nodules are immobile and usually located on the atrial side of the mitral valve and sometimes on the arterial side of the aortic valve. Right-sided lesions are rare. These structural changes may in some cases result in valvular regurgitation. Although valve nodules are detected in most patients with SLE at autopsy, clinically significant valvular heart disease is much less common (1 to 18%). The verrucous valvular

lesions of Libman-Sacks endocarditis are most likely inflammatory in nature and may be associated with the presence of antiphospholipid antibodies. SLE is also a significant risk factor for premature atherosclerosis independent of other cardiovascular risk factors.

Although not specific to SLE, Raynaud phenomenon (Fig. 66-9), characterized by episodic vasospasm and occlusion of the digital arteries in response to cold and emotional stress, is seen in up to 60% of SLE patients and contributes to pain and sometimes necrosis of the distal ends of extremities. The character of the digits classically changes from pallor to cyanosis and then to rubor as vascular perfusion becomes impaired and then reperfusion ensues. In addition, small arteries, arterioles, and capillaries can be affected by vasculitis and fibrinoid necrosis, with clinical manifestations that include periungual telangiectases, abdominal pain, and neuropsychiatric symptoms.

Pulmonary System

Pleuritis, which is the most frequent manifestation of pulmonary involvement in SLE, occurs in about 30% of patients at some point in their disease course. Pleuritis is characterized by pain on respiration and exudative effusions (Chapter 86). Parenchymal disease is less common but may manifest as alveolar hemorrhage (in up to 12% of patients; Chapter 79), pulmonary embolism (Chapter 68) secondary to deep vein thrombosis, or pulmonary hypertension (Chapter 69) with increased pulmonary resistance and impaired diffusing capacity.

Neuropsychiatric Involvement

Clinical features of SLE that involve the nervous system include both neurologic and psychiatric manifestations.[15] About 50% of SLE patients experience a neuropsychiatric event, with 30% of those events attributable to SLE. Both central and peripheral nervous systems can be affected by the disease. The most common manifestations that are probably attributable to SLE cerebritis include cognitive dysfunction, present in 17 to 66% of SLE patients; psychosis or mood disorder, the former reported in up to 8% of patients; cerebrovascular disease in 5 to 18% of patients; and seizures, present in 6 to 51% of patients. Headaches are also common. Although none of these CNS manifestations is found exclusively in SLE, global SLE disease activity is associated with concurrent neuropsychiatric manifestations attributable to SLE.

Cranial nerve and ocular involvement, most likely based on vasculopathy and focal ischemia, can sometimes affect vision. Ocular examination of the retina can reveal cotton-wool spots as a result of retinal ischemia or necrosis. Although rare, transverse myelopathy, frequently associated with antiphospholipid antibodies, can have devastating consequences, including paraplegia. Sensorimotor neuropathies, often asymmetrical, are more common (up to 28%) and are based on damage to small nerve fibers with vasculopathy in the small arteries that supply the nerve fibers.

Gastrointestinal System

Although uncommon, vasculitis of the gastrointestinal tract or mesentery can result in pain and bowel necrosis (Chapter 129). Less common than pleuritis and pericarditis, peritonitis can manifest as peritoneal effusion and abdominal pain. Pancreatitis (Chapter 130) occurs in less than 10% of patients but may also be due to vascular pathology.

Lymphadenopathy and Splenomegaly

About one third of SLE patients demonstrate diffuse lymphadenopathy at some time during the course of their disease (Chapter 154). The nodes are often nontender, and lymphoma is sometimes considered in the differential diagnosis. Biopsy usually reveals follicular hyperplasia, although some histopathologic findings appear similar to the histiocytic necrotizing lymphadenitis that is a feature of Kikuchi disease, a self-limited syndrome characterized by fever and lymphadenopathy. Splenomegaly (Chapter 154) is sometimes seen in SLE, and spleen pathology is characterized by a classic onion-skin histology that appears as concentric circles of collagen matrix surrounding splenic arteries and arterioles.

Hematologic System

In addition to autoantibody specificities that are fairly specific for SLE (anti-DNA, anti-Sm), antibodies that target each of the cellular blood elements are also common. Anemia is present in about 50% of patients and is multifactorial. It can be associated with a positive Coombs test or microangiopathic hemolysis (Chapter 146) or reflect chronic disease (normochromic, normocytic; Chapter 144). Leukopenia (Chapter 153), particularly lymphopenia, is observed, with the lymphocyte count decreasing in the setting of increased disease activity. Antibodies that bind to lymphocytes and neutrophils have been described, and an increased tendency for lymphocytes to undergo spontaneous apoptosis may contribute to lymphopenia. Idiopathic thrombocytopenic purpura (Chapter 158) can be an early manifestation of SLE, and thrombocytopenia induced by antiplatelet autoantibodies can sometimes lead to a life-threatening risk for hemorrhage. Autoantibodies to clotting factors can also occur and contribute to impaired clot formation and hemorrhage. Patients with SLE have a significantly increased risk of developing hematologic malignancies, particularly non-Hodgkin lymphoma (Chapter 171).[16]

Lupus During Pregnancy

Whether pregnancy increases the likelihood of lupus exacerbation has been debated, but lupus flares during pregnancy are rare or mild when disease activity at the time of conception is low and stable. However, patients with SLE have worse fetal outcomes than healthy individuals. Gestational hypertension, fetal growth restriction, and fetal distress are increased in patients with SLE and may lead to fetal loss or premature delivery. Preeclampsia (Chapter 221) can contribute to a poor outcome in both the mother and fetus and can be difficult to distinguish from a lupus flare associated with lupus nephritis.

Antiphospholipid Antibody Syndrome

Antiphospholipid antibodies represent a distinct class of autoantibodies that are seen in about one third of SLE patients but can also be present in individuals who do not carry a diagnosis of SLE (Chapter 160). Whether in primary antiphospholipid syndrome or in SLE, antiphospholipid antibodies are associated with venous and arterial thromboses (Chapter 67). Other clinical manifestations of antiphospholipid syndrome include thrombotic microangiopathic glomerular disease, cardiac valve lesions, livedo reticularis, thrombocytopenia, hemolytic anemia, and CNS disease. These autoantibodies can contribute to fetal loss and growth restriction by binding to the placenta, thereby activating the complement system and inducing inflammation. Catastrophic antiphospholipid syndrome, triggered by the acute onset of multisystemic (three or more organs) thrombosis, is resistant to anticoagulation treatment and is fatal in up to 30% of cases.

DIAGNOSIS

Classification

A careful history of present illness, detailed review of systems and triggering factors, and a family history are essential in raising suspicion for a diagnosis of SLE. Criteria for the classification of patients with SLE (Table 245-2) were designed for research studies[17] but can be helpful for establishing a diagnosis of SLE because they have a sensitivity of 96% and a specificity of 93% for expert-determined SLE. The criteria, which require a positive ANA titer and then weight 10 other features that encompass the various manifestations of

SLE, can be incorporated into an approach for evaluating patients with suspected SLE (Fig. 245-2).[18]

Because drugs can trigger a lupus-like syndrome, a careful drug history should be taken. Procainamide, hydralazine, and anti–tumor necrosis factor inhibitors present the greatest risk for development of lupus, with quinidine, isoniazid, minocycline, and recombinant IFN-α presenting a lower risk.[19]

Laboratory Findings

Laboratory tests are critical for the diagnosis of SLE (Chapter 237). All cellular elements of blood can be affected in lupus, so the complete blood count is an essential test that aids in diagnosis and management. A prolonged activated partial thromboplastin time (aPTT) can indicate the presence of pathogenic antiphospholipid antibodies (Chapter 160).

The erythrocyte sedimentation rate (ESR), although a very nonspecific indicator of systemic inflammation, is often monitored and can provide an indication of disease activity. Interestingly, the C-reactive protein is relatively uninformative in SLE because it is often low in comparison to an ESR.

Assaying and monitoring characteristic lupus serologic tests can strongly support the diagnosis of SLE (Table 245-3) and, in some cases, can assist in the assessment of disease activity. The ANA test, which is positive in virtually all patients and does not need to be repeated after it has been documented to be positive, is commonly considered a requirement for the diagnosis. Anti-double-stranded DNA antibodies are common in SLE, and their titer can be useful in assessing the activity of lupus nephritis. Autoantibodies specific for proteins that associate with nucleic acids in intracellular particles are present in many patients and can provide support for a diagnosis of SLE. Anti-Sm antibodies are highly specific for SLE and, along with anti-RNP antibodies, react with the spliceosome particle. Anti-Ro (SSA) and anti-La (SSB) antibodies are specific for proteins in an RNA-containing particle and are common in patients with Sjögren syndrome and in mothers of babies with neonatal lupus, as well as being a feature of SLE.

Decreased levels of two of the more stable complement components, C3 and C4, are often indicators of enhanced consumption and increased disease activity. Some laboratories also use a functional measure of total hemolytic complement activity (CH_{50}).

Differential Diagnosis

Even with expert guidelines, however, it is the global picture, as provided by a careful history, physical examination, and laboratory data, that supports a diagnosis of SLE.[20] There is considerable heterogeneity among patients, and any one individual may have a different combination of clinical features. At the onset of clinical symptoms, the diagnosis of SLE can be uncertain because many of the systemic manifestations of lupus can mimic other conditions, particularly viral infections or malignancy, and only some of the typical clinical symptoms may be expressed at any one point in time. Important features of SLE are its multisystemic nature and characteristic serology. The differential diagnosis of SLE includes other rheumatic disorders, such as rheumatoid arthritis (Chapter 243) and vasculitis (Chapter 249); infections, including gonococcal arthritis (Chapter 275), parvovirus B19 (Chapter 342), and mononucleosis (Chapter 348); inflammatory bowel disease (Chapter 127); thrombotic thrombocytopenic purpura (Chapter 158); drug reactions (Chapter 234); and malignancies, particularly lymphoma (Chapter 171). The clinical manifestations of lupus can demonstrate overlap with other autoimmune rheumatic diseases and can evolve over time.

Lupus Nephritis

Lupus nephritis is a glomerulonephritis characterized by an active urine sediment and progressive renal impairment. Evaluation of renal disease in

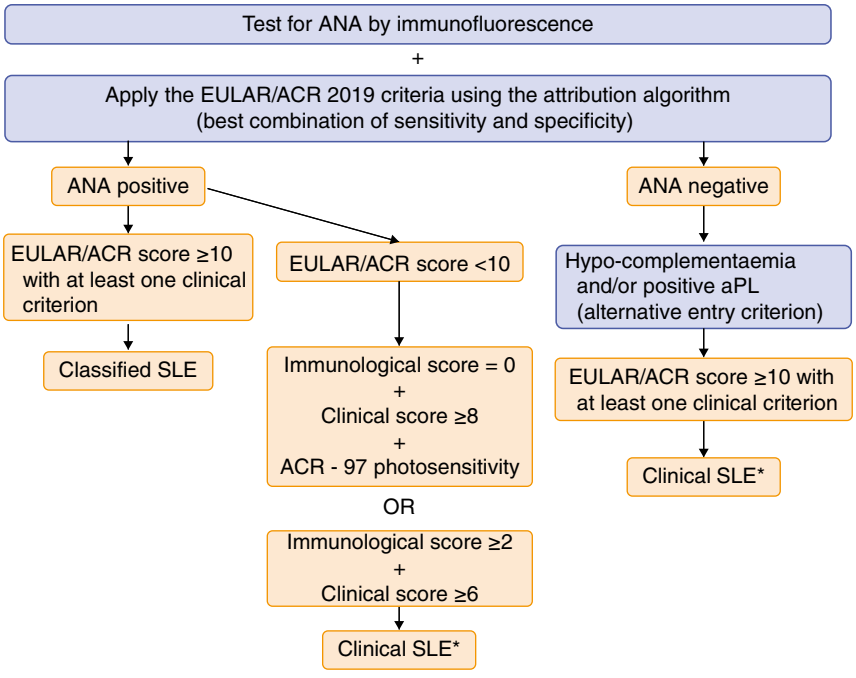

FIGURE 245-2. Diagnostic approach to the patient with suspected systemic lupus erythematosus (SLE). The diagnosis of SLE is clinical, supported by laboratory abnormalities including serologic assays. Diagnostic criteria are not available for SLE, and classification criteria are often used but with several caveats. Among classification criteria, the EULAR/ACR-2019 (Table 245-2) have the best combination of sensitivity and specificity but require positive ANA as an entry criterion. However, patients may be ANA-negative; in such cases, low complement levels and/or positive antiphospholipid antibodies could be used as an alternative entry criterion. For patients who fall short of the classification threshold (i.e., EULAR/ACR score <10), inclusion of photosensitivity or a combination of immunological and clinical features can still be used for SLE diagnosis. ACR = American College of Rheumatology; ANA = antinuclear antibody; EULAR = European League Against Rheumatism; SLE = systemic lupus erythematosus. (From Fanouriakis A, Tziolos N, Bertsias G, et al. Update on the diagnosis and management of systemic lupus erythematosus. *Ann Rheum Dis*. 2021;80:14-25.)

SLE includes urinalysis with microscopic analysis of urine sediment, serum blood urea nitrogen, and creatinine, and a spot urine protein-to-creatinine ratio to estimate protein and creatinine clearance. The glomerular filtration rate (Chapter 100) should be estimated and monitored. A low serum albumin level is consistent with persistent proteinuria and membranous glomerulonephritis, whereas red and white blood cell casts in the urinary sediment suggest a proliferative glomerulonephritis. Renal vein thrombosis can be diagnosed by ultrasonography (Chapter 110).

Renal biopsy provides important information for guiding management and informing prognosis. Renal pathology generally shows the deposition of circulating immune complexes or in situ formation of these complexes in glomeruli (Fig. 245-3). In addition to glomerular inflammation, necrosis, and scarring, renal pathology is characterized by vascular lesions, including thrombotic microangiopathy and extraglomerular vasculitis. Tubulointerstitial disease, including infiltration of the interstitium with mononuclear cells, tubular atrophy, and interstitial fibrosis, may be seen.

Lupus nephritis is classified by biopsy criteria (Table 107-9). Class I and II glomerulonephritis involves mesangial deposition of immune complexes (class I without and class II with mesangial hypercellularity), class III describes focal glomerulonephritis involving less than 50% of total glomeruli, class IV includes diffuse glomerulonephritis involving 50% or more of glomeruli, class V designates membranous lupus nephritis, and class VI is characterized by advanced sclerotic lesions. Pathologic diagnosis should include descriptions of tubulointerstitial and vascular disease as well as glomerular involvement. Several renal pathologic lesions seen in SLE patients but not encompassed in the classification scheme include lupus podocytopathy, collapsing glomerulopathy, and thrombotic microangiopathy, the latter often associated with antiphospholipid syndrome.

Neuropsychiatric Lupus

Evaluation of neuropsychiatric lupus depends on a careful clinical history and physical and laboratory examinations and, in some cases, imaging studies and analysis of cerebrospinal fluid to exclude infection. Magnetic resonance imaging is useful for detecting intracranial abnormalities, which are seen in 19 to 70% of patients and include white matter lesions, cerebral infarction, venous sinus thrombosis, and sometimes atrophy. Magnetic resonance angiography and magnetic resonance spectroscopy can be used to assess cerebral blood flow or neuronal metabolism.

TREATMENT

Counseling and education are fundamental to the treatment of SLE. Patients should be advised to avoid known triggers, such as ultraviolet light, that can exacerbate the disease, and should be instructed regarding the need for adequate rest.

Conventional Medical Therapy

Clinical manifestations of lupus that do not involve major organ systems can often be managed with nonsteroidal anti-inflammatory drugs (Table 26-4), low-dose corticosteroids (Chapter 28), and antimalarials. Oral prednisone in doses ranging from 5 to 30 mg daily is effective in treating constitutional symptoms, arthralgias, pericarditis, pleuritis, and skin disease, and the disease may flare if maintenance doses as low as prednisone at 5 mg daily are discontinued.[A1] Topical corticosteroids are sometimes applied to cutaneous lesions. However, the broad immunosuppression mediated by these drugs contributes to the susceptibility to infection that is an inherent feature of SLE. Osteonecrosis, osteoporotic fractures, posterior subcapsular cataracts, diabetes, myopathy, hypertension, hypoadrenalism, and emotional disturbance are additional deleterious effects of corticosteroids (Chapter 28).[21]

Antimalarial agents, most commonly hydroxychloroquine (administered at 200 to 400 mg/day, with a daily dose ≤5 mg/kg actual body weight), can

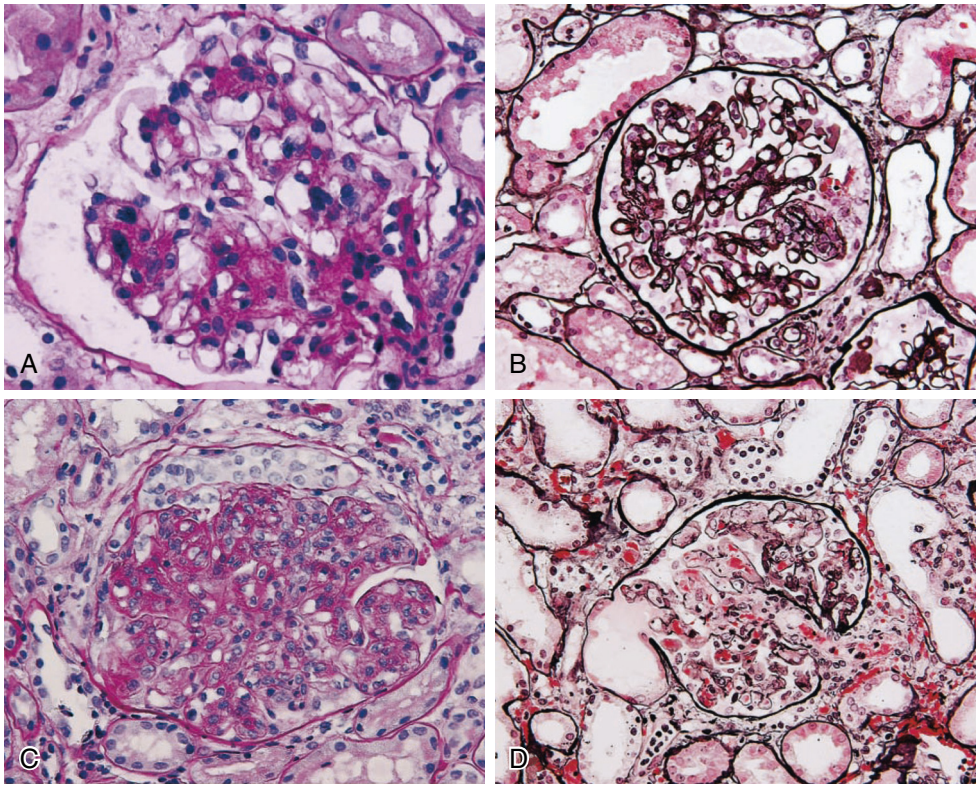

FIGURE 245-3. Histopathology of lupus nephritis. A, Lupus nephritis class II. A glomerulus manifests global endocapillary proliferation, leukocyte influx and apoptotic bodies, double contours, crescent formation with tubular transformation, early sclerosis, and disruption of Bowman capsule (periodic acid–Schiff). **D,** Thrombotic microangiopathy in a patient with systemic lupus erythematosus and circulating lupus anticoagulant. A glomerulus shows severe capillary and arteriolar thrombosis, endothelial cell swelling and necrosis, neutrophil influx, and stasis of erythrocytes. No signs of immune deposits were found (methenamine silver). (From Wenning JJ, D'Agati VD, Schwartz MM, et al. The classification of glomerulonephritis in systemic lupus erythematosus revisited. *J Am Soc Nephrol*. 2004;15:241.)

control skin involvement and arthralgias and are routinely used in most lupus patients. Hydroxychloroquine has been associated with a decreased incidence of thrombosis, a mechanism that could affect vasculopathy and end-organ damage. Antimalarials are generally well tolerated. The most serious toxicity is retinal damage, with the risk increasing at higher cumulative exposures.[22] Ophthalmologic examinations should precede initiation of therapy and be repeated every 12 months thereafter.

Management of Serious Organ-System Disease

Lupus flares involving rapid decompensation of renal function, CNS disease (including seizures, strokes, or psychosis), or widespread vasculitis or vasculopathy can be life-threatening and must be recognized and treated early and aggressively. Careful attention to monitoring for concurrent or superimposed infection is an important priority during management of a severe lupus flare, and distinguishing sepsis from active lupus or catastrophic antiphospholipid syndrome can be a particular challenge.

For more serious disease, particularly active nephritis, CNS disease, or systemic vasculitis, a traditional approach for initial therapy has been prednisone (60 mg daily) or intravenous methylprednisolone (1 g daily for 3 days), but recent recommendations suggest lower doses in combination with other medications. For new-onset proliferative lupus nephritis, the recommended initial treatment is mycophenolate mofetil (target dose of 2 to 3 g daily) or low-dose cyclophosphamide (500 mg intravenously every 2 weeks for 6 doses) plus intravenous methylprednisolone (500 to 2500 mg) over 1 to 3 days followed by oral prednisone (0.3 to 0.5 mg/kg/day)[23] (Fig. 245-4). Multitarget therapy with tacrolimus (4 mg per day), mycophenolate mofetil (1 g per day), and 3 days of pulse methylprednisolone followed by oral prednisone provides superior efficacy compared with intravenous cyclophosphamide as induction therapy for lupus nephritis.[A2] Tacrolimus is noninferior compared with mycophenolate mofetil when combined with high-dose prednisolone for induction therapy.[A3] Voclosporin (23.7 mg orally twice daily) and belimumab (10 mg/kg intravenously every 2 weeks for three doses followed by 10 mg/kg every 4 weeks or 400 mg subcutaneously weekly for four doses then 200 mg weekly) in combination with background immunosuppressive agents can increase the likelihood of a clinical response in lupus nephritis.[A4–A6] Current recommendations are to reduce the prednisone dose to 7.5 mg or less daily by 3 to 6 months after initiation of therapy.

For maintaining improvement in patients who have responded to induction therapy, current data favor mycophenolate mofetil over azathioprine.[A7] Rituximab, a B-cell–depleting monoclonal antibody targeting CD20, is sometimes used in patients who are refractory to recommended therapies. A second-generation anti-CD20 monoclonal antibody, obinutuzumab, is also a promising option.[A8] As these and other new therapies emerge, recommendations of professional societies are likely to evolve.

A similar approach to that used for proliferative lupus nephritis can be applied to other serious clinical disease flares. In general, cyclophosphamide can be added to high-dose corticosteroid therapy in the setting of severe flare, although mycophenolate mofetil has gained increased use in situations in which the physician or patient wishes to avoid the potential toxicities associated with cyclophosphamide. The symptoms and effusions associated with pericarditis are quite responsive to moderate-dose (20 to 30 mg/day of prednisone) corticosteroid treatment.

Belimumab is increasingly used in patients with moderate and sustained disease activity.[A9,A10] Anifrolumab (300 mg intravenously every 4 weeks) is a monoclonal antibody that reacts with the type I interferon receptor and is approved by the U.S. FDA to treat patients with moderate to severe SLE.[A11,A12] Janus-associated kinase inhibitors (e.g., deucravacitinib),[A13] an inhibitor of CD40 ligand (dapirolizumab pegol),[A14] low-dose IL-2 (to promote expansion of T regulatory cells),[A15,A16] and other promising agents are under investigation.[24]

Specific Immunosuppressive Therapies

Alkylating Agents

Approximately 33% of lupus patients receive cytotoxic therapy during the course of their disease. Cyclophosphamide (Chapter 28; 0.5 to 1 g/m^2 body surface area administered intravenously monthly for 6 months, followed by quarterly doses through 2 years) is usually given with oral prednisone in tapering doses or sometimes with pulse methylprednisolone. Although this regimen is often effective in controlling glomerulonephritis, overall patient survival has not been demonstrated to be increased, and high-dose cyclophosphamide is associated with significant toxicity, including cytopenia, infection, and gonadal failure. A modified therapeutic regimen for administration of cyclophosphamide, termed the "Euro-lupus regimen," involves 500 mg administered intravenously every 2 weeks for six doses, followed by

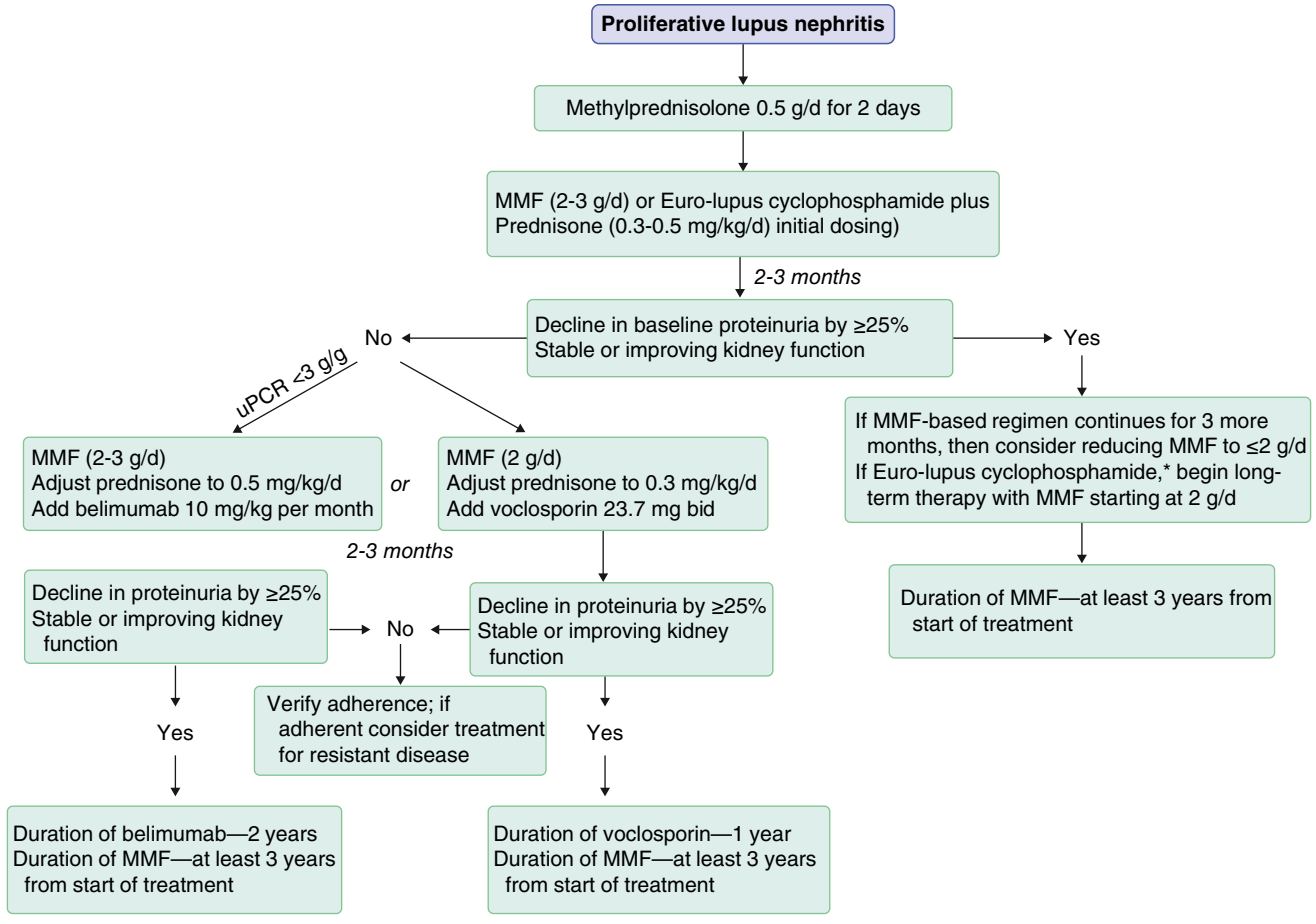

FIGURE 245-4. Algorithm for medical management of proliferative lupus nephritis. *Euro-lupus cyclophosphamide refers to the regimen described in the text and in Tamirou F, Husson SN, Gruson D, et al. Brief report: the Euro-lupus low-dose intravenous cyclophosphamide regimen does not impact the ovarian reserve as measured by serum levels of anti-Müllerian hormone. *Arthritis Rheumatol*. 2017;69:1267-1271. MMF = mycophenolate mofetil; uPCR = urine protein : creatinine ratio. (From Mejia-Vilet JM, Malvar A, Arazi A, et al. The lupus nephritis management renaissance. *Kidney Int*. 2021:S0085-2538:00874-7.)

mycophenolate mofetil or azathioprine. This approach provides long-term efficacy comparable to the high-dose cyclophosphamide regimen and is superior in maintaining ovarian reserve. Cyclophosphamide is relatively contraindicated in pregnant women and should be discontinued 3 months before conception.

Purine Synthesis Inhibitors

Azathioprine (Chapter 28; 2 to 3 mg/kg/day administered as a tablet) has been used for the treatment of lupus nephritis and as a steroid-sparing agent in SLE for many years. Toxicities target the bone marrow, where they result in cytopenias, as well as the liver. Azathioprine is rarely associated with non-Hodgkin lymphoma (Chapter 171), but it has been used safely in pregnant women.

Mycophenolate mofetil is equivalent to pulse low-dose intravenous cyclophosphamide for induction therapy in lupus nephritis.[A17] Mycophenolate mofetil (1 g twice daily) is more effective than azathioprine for the maintenance treatment of lupus nephritis, with treatment failure rates reduced from 32 to 16%. As with cyclophosphamide, mycophenolate mofetil should not be used in pregnancy and should be discontinued at least 6 weeks prior to conception.

Methotrexate

Methotrexate (Chapter 28; 15 to 25 mg/week orally for 6 months) can help control SLE and allow tapering of prednisone. The most responsive clinical manifestations are cutaneous and articular. Methotrexate should not be used in pregnancy.

Calcineurin Inhibitors

Tacrolimus (0.1 mg/kg/day in two divided doses) and cyclosporine (often started at 4 mg/kg/day with gradual lowering to 2 mg/kg/day) are oral calcineurin inhibitors used in treatment of some patients with lupus nephritis.[25,A18,A19] Voclosporin (23.7 mg twice daily) with background immunosuppressive therapy is also effective in lupus nephritis.

Biologic Therapies

Belimumab, a monoclonal antibody that blocks B-cell survival, is currently being used along with background therapy in patients with moderately active SLE and in some patients with lupus nephritis. When added to standard therapy, belimumab significantly improves response rates, reduces the activity of disease, and is generally well tolerated in SLE.

Rituximab has not been efficacious in controlled trials but nevertheless is increasingly used in patients whose lupus nephritis or cytopenias are refractory to conventional therapies.[26] Obinutuzumab (an anti-CD20 monoclonal antibody with improved capacity for B-cell depletion) is under study for treatment of lupus nephritis. Anifrolumab, a monoclonal antibody specific for the type I IFN receptor, is approved for the treatment of moderate to severe SLE in the setting of background standard of care therapy.

Intravenous Gamma Globulin

Although positive data from controlled trials of intravenous gamma globulin are not available, pooled IgG fractions can sometimes be efficacious in gaining control of lupus that is refractory to other therapies. A common regimen is 2 g/kg in divided doses over a 3- to 5-day period.

Plasmapheresis

Removal of pathogenic antibodies and immune complexes is the goal of plasmapheresis. Despite scant data, plasmapheresis has occasionally been useful in lupus patients with life-threatening complications, such as thrombotic thrombocytopenic purpura (Chapter 158), in which the clinical manifestations can be clearly attributed to pathogenic autoantibodies.

Adjunctive Therapies

In addition to controlling autoimmunity and inflammation, it is essential to control hypertension with an angiotensin inhibitor or an angiotensin receptor blocker (Tables 64-7 and 64-9). In patients with a history of thrombosis, who will usually have antiphospholipid antibodies, long-term warfarin (Chapter 67) is recommended.

Contraception and Pregnancy

Pregnancy should be undertaken with caution, careful monitoring, and the goal of minimizing activity of the disease at the time of conception. In lupus patients whose disease is stable or of low activity and who do not have antiphospholipid antibodies, data indicate that oral contraceptive agents do not contribute to disease exacerbations. Patients with moderate or severe disease activity are advised to use progestin-only oral contraceptive agents (Table 220-2) or an intrauterine device.[27] Hydroxychloroquine may reduce the risk of heart block in fetuses of pregnant mothers with SLE.[28]

PROGNOSIS

Although survival of patients with a diagnosis of SLE is good, lupus remains a potentially fatal disease. SLE demonstrates a bimodal pattern of death, with deaths within the first year attributable to active lupus and infection, whereas late deaths are mostly attributable to atherosclerotic cardiovascular disease. The incidence rate ratio of death is four times greater in patients whose disease is initially severe compared with patients whose disease is initially mild.[29]

After a diagnosis of SLE has been made, prolonged complete remission is achieved in fewer than 10% of patients. Predictors of high lupus disease activity include Hispanic and Black ethnicities, lack of health insurance, and poor social support. Anti-double-stranded DNA antibodies also predict high levels of disease activity.

The prognosis of class I and class II renal disease is usually good, whereas class IV, the most common form of lupus nephritis, has the worst prognosis, particularly when the serum creatinine level is elevated at the time of diagnosis. Class V nephritis occurs in 10 to 20% of patients, and the implication for long-term outcome depends on the degree of proteinuria, with mild proteinuria having a good prognosis and nephrotic syndrome with chronic edema having a worse prognosis. About 20 to 25% of patients with lupus nephritis develop end-stage renal disease by 15 years after diagnosis, and an initially high serum creatinine (>1.5 mg/dL) is a predictor of progression to end-stage disease.[30]

Premature atherosclerotic disease represents a significant contributor to morbidity and mortality in SLE patients,[31] and mortality from atherosclerosis may be up to 10 times greater in patients with SLE than in age- and sex-matched controls. Patients with SLE have an increased risk for hematologic malignancies, particularly non-Hodgkin lymphoma (Chapter 171). Prognostic factors for an adverse fetal outcome in pregnant mothers with lupus are maternal renal disease and hypertension.

246 SYSTEMIC SCLEROSIS (SCLERODERMA)

JOHN VARGA

SYSTEMIC SCLEROSIS

DEFINITION

Systemic sclerosis, originally termed *scleroderma*, is a chronic autoimmune disease of unknown cause associated with considerable morbidity and mortality. The disease shows marked clinical heterogeneity, has protean clinical manifestations, and may follow a stable, indolent, or rapidly progressive course. The hallmark of systemic sclerosis is thickening and hardening of the skin (scleroderma), but the lungs, gastrointestinal tract, kidneys, heart, tendons, and ligaments are also commonly affected.

EPIDEMIOLOGY

Systemic sclerosis is a sporadic disease with a worldwide distribution.[1] It is considered an orphan disease in the United States, with an incidence of 9 to 19 cases per million per year. Systemic sclerosis shows a marked female predominance, particularly in the childbearing years. The peak age of onset is 40 to 60 years for both the limited and diffuse cutaneous forms. Blacks have a higher incidence and an earlier age of disease onset compared with Whites, and they are more likely to have the diffuse cutaneous form of systemic sclerosis associated with interstitial lung involvement and a worse prognosis.

The occupational exposure most strongly linked with systemic sclerosis is crystalline silica (sandblasting, mining, ceramic, clay, and glass manufacturing). Other tentative causal exposures include polyvinyl chloride, epoxy resins, and aromatic hydrocarbons including toluene and trichloroethylene. Certain drugs, including bleomycin, pentazocine, hormone replacement therapy, cocaine, and appetite suppressants, have been anecdotally linked with systemic sclerosis or pulmonary arterial hypertension. Although early studies implied a putative association of silicone breast implants with systemic sclerosis, large-scale epidemiologic investigations failed to establish an increased risk.

PATHOBIOLOGY

Genetic Factors

Among patients with systemic sclerosis, 1.6% have a first-degree relative with systemic sclerosis, a prevalence rate that is substantially higher than in the general population (0.026). Indeed, a family history is recognized as the strongest identified risk factor for systemic sclerosis. Additionally, patients with systemic sclerosis are more likely to have first-degree relatives with Raynaud phenomenon, interstitial lung disease, or other autoimmune diseases including multiple sclerosis, rheumatoid arthritis, and thyroiditis. Genomewide association and candidate-gene studies have identified significant genetic

Contraception and Pregnancy

Pregnancy should be undertaken with caution, careful monitoring, and the goal of minimizing activity of the disease at the time of conception. In lupus patients whose disease is stable or of low activity and who do not have antiphospholipid antibodies, data indicate that oral contraceptive agents do not contribute to disease exacerbations. Patients with moderate or severe disease activity are advised to use progestin-only oral contraceptive agents (Table 220-2) or an intrauterine device.[27] Hydroxychloroquine may reduce the risk of heart block in fetuses of pregnant mothers with SLE.[28]

PROGNOSIS

Although survival of patients with a diagnosis of SLE is good, lupus remains a potentially fatal disease. SLE demonstrates a bimodal pattern of death, with deaths within the first year attributable to active lupus and infection, whereas late deaths are mostly attributable to atherosclerotic cardiovascular disease. The incidence rate ratio of death is four times greater in patients whose disease is initially severe compared with patients whose disease is initially mild.[29]

After a diagnosis of SLE has been made, prolonged complete remission is achieved in fewer than 10% of patients. Predictors of high lupus disease activity include Hispanic and Black ethnicities, lack of health insurance, and poor social support. Anti-double-stranded DNA antibodies also predict high levels of disease activity.

The prognosis of class I and class II renal disease is usually good, whereas class IV, the most common form of lupus nephritis, has the worst prognosis, particularly when the serum creatinine level is elevated at the time of diagnosis. Class V nephritis occurs in 10 to 20% of patients, and the implication for long-term outcome depends on the degree of proteinuria, with mild proteinuria having a good prognosis and nephrotic syndrome with chronic edema having a worse prognosis. About 20 to 25% of patients with lupus nephritis develop end-stage renal disease by 15 years after diagnosis, and an initially high serum creatinine (>1.5 mg/dL) is a predictor of progression to end-stage disease.[30]

Premature atherosclerotic disease represents a significant contributor to morbidity and mortality in SLE patients,[31] and mortality from atherosclerosis may be up to 10 times greater in patients with SLE than in age- and sex-matched controls. Patients with SLE have an increased risk for hematologic malignancies, particularly non-Hodgkin lymphoma (Chapter 171). Prognostic factors for an adverse fetal outcome in pregnant mothers with lupus are maternal renal disease and hypertension.

Genomewide association and candidate-gene studies have identified significant genetic

ABSTRACT

Systemic sclerosis is a chronic autoimmune connective tissue disease. It is more common in women and typically has an onset in the post-reproductive years. The etiology is unknown, and familial inheritance is uncommon; however, a number of genetic variants have been associated with an increased disease risk. The disease is characterized by distinct and unique autoantibodies: fibrosis in the skin accompanied by fibrosis in the lungs, gut, heart, and most internal organs, and an obliterative noninflammatory microangiopathy. Together, these pathologic processes lead to the hallmark clinical manifestations of systemic sclerosis, including skin tightness, joint contractions, lung fibrosis, pulmonary artery hypertension, Raynaud phenomenon, digital ischemic ulcers, calcinosis cutis, and intestinal dysmotility. Renal crisis with malignant hypertension and renal failure is an uncommon but deadly complication of systemic sclerosis. The risk of certain malignancies appears to be increased. Patients with systemic sclerosis show substantial variability in the clinical manifestations, rate of disease progression, autoantibody profiles, treatment responses, and outcomes. Current therapies are primarily immunomodulatory. However, organ-specific therapies are effective in reducing symptoms, thereby mitigating complications and improving quality of life. Early accurate diagnosis, recognition of specific complications, risk stratification, and individualized management improve outcomes.

microangiopathy

association of systemic sclerosis with multiple human leukocyte antigen (HLA) loci. Non-HLA risk loci associated with systemic sclerosis include *STAT4, IRF4, PTPN22, TNFAIP3, TNIP-1, IRAK1, CD247*, and *BANK1*, each of which encodes genes involved with immune signaling or autoimmunity. Most of these genetic risk alleles are not unique for systemic sclerosis, and are also linked with other autoimmune diseases, particularly systemic lupus erythematosus.

Pathology

The protean clinical and pathologic manifestations of systemic sclerosis reflect a complex underlying biology encompassing three interrelated cardinal pathomechanistic processes: autoimmunity and inflammation, vascular injury and obliteration, and fibrosis with excessive matrix accumulation and loss of function in multiple tissues and organs (E-Fig. 246-1).

The distinguishing pathologic hallmark of systemic sclerosis is the constellation of capillary loss (rarefaction) and obliterative vasculopathy coexisting with fibrosis in most organs. In early-stage disease, perivascular inflammation can be seen even before the appearance of fibrosis. The vascular lesion is characterized by intimal proliferation in the small- and medium-sized arteries, thereby resulting in luminal narrowing and obliteration, and is commonly complicated by platelet activation and hypercoagulability. In later-stage systemic sclerosis, noninflammatory fibrosis is prominent in the skin, lungs, gastrointestinal tract, heart, tendon sheath, perifascicular tissue surrounding skeletal muscle, and some endocrine organs such as the thyroid gland. Accumulation of connective tissue rich in fibrillar collagens, fibronectin, tenascin, cartilage oligomeric matrix protein, and proteoglycans disrupts normal architecture.

In the skin, dermal collagen deposition causes obliteration of the hair follicles, sweat glands, and other adnexae. Fibrosis invades the subjacent white dermal adipose layer with entrapment of fat cells (adipocytes). The epidermis is atrophic, and the rete pegs are effaced. In late-stage disease, there is a paucity of vascular and lymphatic endothelium. In the lungs, the interstitium and alveolar spaces are infiltrated with inflammatory cells in early disease. With progression, interstitial fibrosis and vascular damage, often coexisting within the same lesions, dominate the pathologic picture. Progressive thickening of the alveolar septae results in obliteration of the air spaces, honeycombing, and loss of pulmonary blood vessels.

Intimal thickening of small pulmonary arteries (E-Fig. 246-2), best seen with elastin stain, underlies pulmonary arterial hypertension (Chapter 69). These vascular lesions resemble the changes seen in idiopathic pulmonary arterial hypertension, but the hallmark plexiform lesions are uncommon in systemic sclerosis. In the gastrointestinal tract, pathologic changes can be found at any level from the mouth to the rectum.[2,3] Fibrosis of the lamina propria and submucosa with atrophy of the muscular layers are prominent in the lower esophagus, whereas striated muscle in the upper third of the esophagus is generally spared (Chapter 124). Replacement of the normal gut architecture leads to disordered peristaltic activity with gastroesophageal reflux and dysmotility, gastroparesis, and small bowel obstruction. Chronic reflux can be complicated by esophageal inflammation, ulcerations, stricture formation, and Barrett metaplasia.

Pathologic changes in the myocardium and pericardium are common in systemic sclerosis, even in patients with no clinical evidence of cardiac involvement. Characteristic microvascular lesions include concentric intimal hypertrophy and luminal narrowing. Contraction band necrosis reflecting ischemia-reperfusion injury is prominent and may be accompanied by patchy myocardial fibrosis. In the kidneys, noninflammatory lesions occur in the interlobular arteries. Scleroderma renal crisis[4] (Chapter 110) is associated with striking changes in small renal arteries, with reduplication of elastic lamina, marked intimal proliferation, and concentric narrowing of the lumen (onion-skin), frequently accompanied by thrombotic microangiopathy with thrombosis and microangiopathic hemolysis.

Vasculopathy, Immune Dysregulation, and Fibrosis

Vasculopathy

Early vascular injury affects primarily the small- and medium-sized arteries and arterioles in multiple vascular beds. Endothelial cell injury and apoptosis result in altered balance of endothelium-derived vasodilatory (nitric oxide and prostacyclin) and vasoconstricting (endothelin-1) molecules, vascular permeability, and upregulation of adhesion molecules with transendothelial leukocyte diapedesis. Increased reactivity of platelets, activation of intravascular coagulation, defective fibrinolysis, and the resulting thrombosis further compromise vascular function. Injured capillaries lose their pericyte coverage and degenerate, thereby resulting in capillary rarefaction. Small blood vessels show intimal hyperplasia with thickening and reduplication of the basement membrane. Upon injury, endothelial cells undergo reprogramming through endothelial-mesenchymal transition. In the vascular media, myointimal cells proliferate, whereas the adventitial layers develop fibrosis. The net result is obliteration of capillaries, arterioles, and even large vessels, impaired blood flow and widespread tissue ischemia. Recurrent ischemia-reperfusion is associated with the generation of reactive oxygen species that further damage the endothelium.

Raynaud Phenomenon

The most characteristic and generally earliest vascular complication of systemic sclerosis is Raynaud phenomenon (Chapter 66),[5] which reflects abnormal thermal regulation of blood flow. Autonomic and peripheral nervous system changes in patients with Raynaud phenomenon are associated with impaired production of calcitonin gene–related peptide from sensory afferent nerves and heightened sensitivity of α_2-adrenergic receptors on vascular smooth muscle cells. In contrast to *primary* Raynaud phenomenon (also called Raynaud disease), which is a common and relatively benign condition, *secondary* Raynaud phenomenon is generally progressive and frequently complicated by vascular remodeling with irreversible structural changes that result in tissue damage.

Inflammation and Autoimmunity

Cellular Immunity

Immune dysregulation is a hallmark systemic sclerosis shares with other autoimmune diseases. In early disease, T cells, B cells, dendritic cells, and monocyte-macrophages are activated and accumulate within lesional tissues.

Tissue-infiltrating $CD4^+$ T cells display restricted TcR receptor signatures indicative of their oligoclonal expansion in response to unknown antigens. T cells show T_H2 polarization with secretion of interleukin (IL)–4, IL-13, and IL-21, and low levels of interferon (IFN)–γ. T_H2 cytokines induce TGF-β and promote the synthesis of collagen and other extracellular matrix molecules.[6] In early-stage systemic sclerosis, a predominant cytotoxic CD4 T cell accumulation may contribute to endothelial apoptosis.

Myeloid dendritic cells in systemic sclerosis show abnormally high secretion of inflammatory cytokines and chemokines such as CXCL. Macrophages are often prominent in early skin and lung lesion. Elevated expression of type I interferon-regulated genes (IFN signature) in systemic sclerosis is consistent with innate immune activation and may contribute to vascular injury.

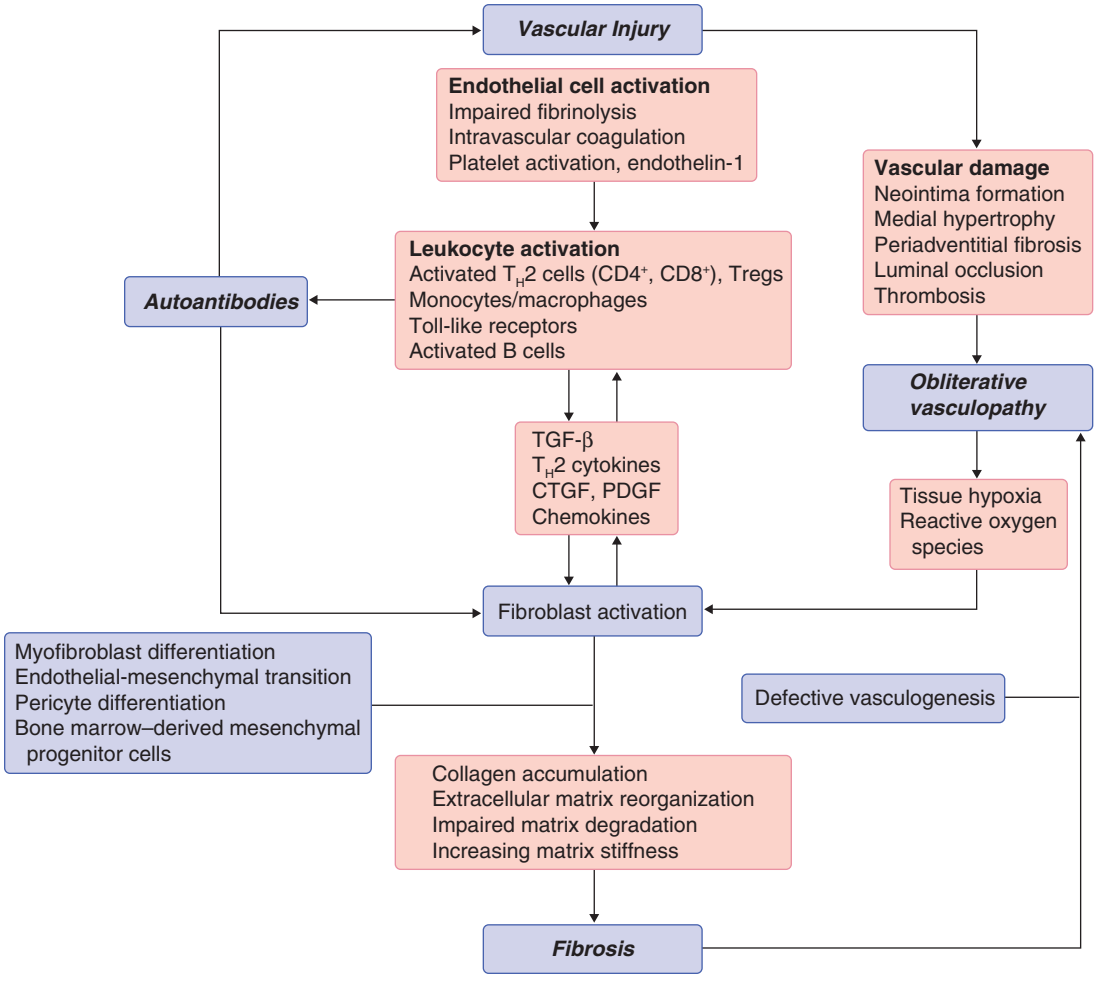
Humoral immunity and autoantibodies

Evidence of B-cell dysregulation is prominent in systemic sclerosis,[7] and most patients have antinuclear antibodies, and a number of disease-specific autoantibodies. These autoantibodies have clinical utility as diagnostic and prognostic markers (Table 246-1). Systemic sclerosis–specific autoantibodies are commonly directed against intracellular proteins, such as topoisomerase-I, centromere, and RNA polymerases I and III. Autoantibodies directed against endothelial cells or recognizing cell surface receptors (platelet-derived growth factor receptor [PDGFR], angiotensin II receptor, and endothelin-1 receptor), and other antigens, including telomere-related proteins, have been reported in systemic sclerosis. B-cell alterations are implicated in mediating both the autoimmune and fibrotic components of systemic sclerosis.

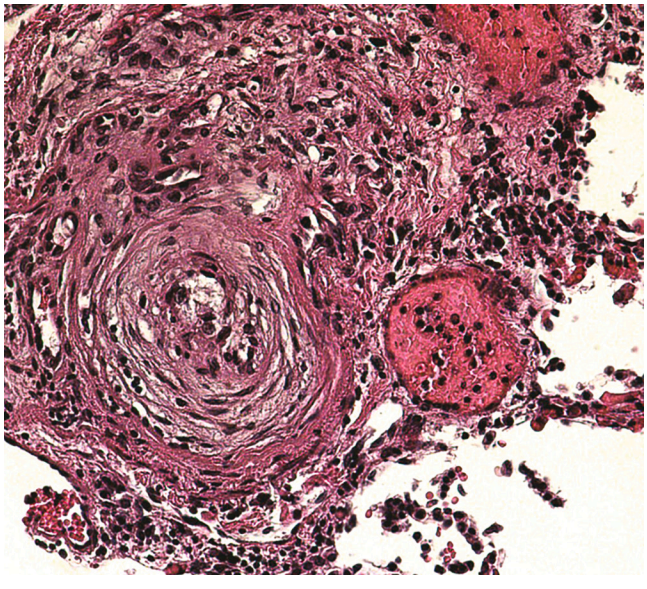
Fibrosis

Fibrosis synchronously affecting the skin and multiple internal organs distinguishes systemic sclerosis from other rheumatic diseases. Fibrosis is characterized by the accumulation of a collagen-rich and rigid extracellular matrix elaborated by resident fibroblasts and myofibroblasts, and the replacement of tissue architecture disrupting normal function.

Myofibroblasts, which are smooth muscle cell–like mesenchymal cells with both contractile and biosynthetic properties, characterize all forms of fibrosis. Myofibroblasts normally appear transiently in damaged tissue to promote wound healing through production of extracellular matrix and of TGF-β, as well as contraction of the surrounding tissue. In systemic sclerosis, activated myofibroblasts accumulate within lesional tissue through one of three pathways: (1) in situ activation of quiescent resident fibroblasts, (2) reprogramming of injured epithelial, endothelial cells, and pericytes, or (3) differentiation of circulation-derived monocytic progenitor cells. Within the fibrotic tissue, activated myofibroblasts evade apoptosis.



E-FIGURE 246-1. The tripartite pathogenesis of systemic sclerosis: vasculopathy, autoimmunity, fibrosis. Initial vascular injury in a genetically susceptible individual is the likely primary event of systemic sclerosis. Injury leads to vascular damage, inflammation, and autoimmunity. The inflammatory and immune responses generate cytokines and growth factors that further damage the endothelium and trigger fibroblast activation that underlies extracellular matrix remodeling and intractable fibrosis. Vasculopathy, loss of microvasculature, and reduced blood flow result in ischemia and oxidative stress that further aggravate vascular damage, tissue fibrosis, and atrophy. CTGF = connective tissue growth factor; PDGF = platelet-derived growth factor; TGF-β = transforming growth factor–β.



E-FIGURE 246-2. Pulmonary artery obliterative vasculopathy coexisting with fibrosis. Striking intimal hyperplasia and narrowing of the lumen of a small pulmonary artery, coexisting with interstitial pulmonary fibrosis, in a patient with systemic sclerosis.

CLINICAL MANIFESTATIONS

Virtually every organ can be affected in systemic sclerosis, but the relative frequency, tempo, and severity shows considerable patient-to-patient variability. Patients with limited cutaneous systemic sclerosis commonly present with long-standing Raynaud phenomenon, limited skin involvement, and insidious progression of internal organ disease. Patients with diffuse cutaneous systemic sclerosis characteristically develop extensive skin induration and joint stiffness associated with early-onset internal organ involvement (Table 246-2). However, many patients with systemic sclerosis defy easy classification, or show overlap with clinical and laboratory evidence of another autoimmune disease such as polymyositis (Chapter 248), Sjögren syndrome (Chapter 247), inflammatory polyarthritis (Chapter 240), or systemic lupus erythematosus (Chapter 245).

Initial Clinical Presentation

Diffuse Cutaneous Systemic Sclerosis

Patients with diffuse cutaneous systemic sclerosis typically present with puffy fingers, erythema, and pruritus, often accompanied by fatigue, stiffness, muscle weakness, and carpal tunnel syndrome. Raynaud phenomenon may not be present until later in the disease. Over weeks to months, the inflammatory edematous phase evolves into a chronic "fibrotic" phase with skin induration accompanied by dryness, hyperpigmentation, loss of body hair, and impaired sweating. Advancing skin changes commonly herald onset of internal organ involvement that is most rapidly progressive during the initial 4 years from disease onset. Thereafter, the risk for new organ involvement subsides.

Limited Cutaneous Systemic Sclerosis

In patients with limited cutaneous systemic sclerosis, the diagnosis is generally made at a later stage of the disease. Patients often have a long-standing history of Raynaud phenomenon, sometimes complicated by ischemic ulcerations at the fingertips. Disease course is indolent, with insidious progression of gastroesophageal reflux, mucocutaneous telangiectasia, or soft tissue calcinosis. Vascular manifestations tend to be more pronounced in limited cutaneous systemic sclerosis compared with diffuse cutaneous systemic sclerosis, whereas scleroderma renal crisis is uncommon.

Organ Involvement

Skin

Skin thickening typically starts in the distal fingers and is generally preceded by puffy fingers and hands. Skin involvement typically advances in a centripetal pattern from distal extremities. The skin may be hyperpigmented, but dark-skinned individuals may develop vitiligo-like "salt-and-pepper" changes which is most prominent on the scalp, upper back, and chest. Obliteration of eccrine and sebaceous glands decreases sweating and oil secretion, thereby causing dry and itchy skin. Facial changes include a beaklike nose, thinning and retraction of the lips, fine wrinkles (rhytids, radial furrowing) around the mouth, and occasionally a masklike facies due to reduced mobility of the eyelids, cheeks, and mouth (Fig. 246-1). Decreased oral aperture (microstomia) is common and can interfere with eating and oral hygiene.

In long-standing systemic sclerosis, the skin is atrophic and tethered to the underlying tissue. Telangiectasias due to dilation of postcapillary venules in the upper dermis are prominent on the face, hands, lips, and oral mucosa. Breakdown of atrophic skin can lead to painful and nonhealing ulcerations at the extensor surfaces of the interphalangeal joints, fingertips, and bony prominences such as the elbows and malleoli. Ischemic ulcerations at the fingertip heal slowly, may become secondarily infected, and give rise to pathognomonic digital tip "pitting." Ischemic soft tissue loss at the fingertips is associated with bony resorption of the terminal phalanges (acro-osteolysis) (Fig. 246-2).

Calcinosis of the skin and soft tissues is common. Concrete deposits composed of calcium hydroxyapatite crystals vary in size from tiny punctate lesions to large conglomerate masses. They can be readily visualized on plain radiographs and precisely localized and measured with dual-energy CT imaging (Fig. 246-3).

Common locations for calcinosis cutis include the hands (finger pads), extensor surfaces of the forearms, and olecranon and prepatellar bursae. Calcific deposits can ulcerate through the overlying skin, producing drainage of chalky white material, pain, and local inflammation, and may become secondarily infected.

Raynaud Phenomenon

Raynaud phenomenon (Chapter 66) is an episodic vasospastic event in virtually all patients with systemic sclerosis.[8] Typical attacks start with pallor

TABLE 246-1 CHARACTERISTIC SYSTEMIC SCLEROSIS-ASSOCIATED AUTOANTIBODIES

AUTOANTIBODY FREQUENCY	SUBSET	CHARACTERISTIC CLINICAL ASSOCIATION
Topoisomerase-I (10-40%; also called Scl-70)	Diffuse cutaneous (less commonly limited)	Tendon friction rubs, ILD, cardiac involvement, scleroderma renal crisis; isolated PAH rare
Centromere (15-40%)	Limited cutaneous	Digital ischemia, calcinosis cutis, isolated PAH, PBC; severe ILD and scleroderma renal crisis rare
RNA polymerase III (4-25%)	Diffuse cutaneous	Extensive skin involvement; tendon friction rubs, scleroderma renal crisis, increased cancer risk
U3-RNP/fibrillarin (1-5%)	Diffuse cutaneous	PAH, ILD, myositis
Th/To (1-7%)	Limited cutaneous	ILD, isolated PAH
PM/Scl (0-6%)	Limited cutaneous	Calcinosis cutis, myositis, arthritis
U1-RNP (5-35%)	MCTD	Severe PAH, myositis

ILD = interstitial lung disease; MCTD = mixed connective tissue disease; PAH = pulmonary arterial hypertension; PBC = primary biliary cirrhosis; RNP = ribonucleoprotein.

TABLE 246-2 CLASSIFICATION OF SYSTEMIC SCLEROSIS

CHARACTERISTIC FEATURES	DIFFUSE CUTANEOUS SYSTEMIC SCLEROSIS	LIMITED CUTANEOUS SYSTEMIC SCLEROSIS
Skin induration	Diffuse: fingers, extremities, face, trunk; progression rapid; tendon friction rubs	Limited to fingers, distal to elbows, face; progression slow
Raynaud phenomenon	Onset occurs coincident with or subsequent to skin involvement	Precedes skin involvement; often severe; associated with critical ischemia
Pulmonary fibrosis	Frequent, early, can be progressive and severe	Occasional, rarely severe
Pulmonary arterial hypertension	Occasional, commonly in association with pulmonary fibrosis	Frequent, late, may be isolated
Scleroderma renal crisis	Occurs in up to 15%; early	Very rare
Calcinosis cutis	Infrequent	Frequent, prominent
Characteristic autoantibodies	Anti-topoisomerase I (Scl-70), anti-RNA polymerase III	Anticentromere

(vasoconstriction) followed by cyanosis (ischemia) and erythema (reperfusion), commonly triggered by exposure to cold or emotional stress.

Distinguishing primary from secondary Raynaud can present a challenge. Compared to primary, secondary Raynaud typically develops at an older age (>30 years) and tends to be more severe. Nailfold capillaroscopy is a useful noninvasive bedside method for visualizing cutaneous capillaries using an ophthalmoscope. Patients with primary Raynaud phenomenon have capillaries that appear as regularly spaced parallel vascular loops at the nailfolds, whereas in systemic sclerosis, capillaries are distorted with widened and irregular loops, dilated lumen, areas of vascular "dropout," and microhemorrhages (Fig. 246-2A).

Gastrointestinal Involvement

Gastrointestinal tract involvement is very common in patients with both limited and diffuse cutaneous systemic sclerosis, and when severe, is a marker of poor prognosis. Smooth muscle atrophy and obliterative small vessel vasculopathy with or without fibrosis throughout the length of the gastrointestinal tract underlies altered peristaltic activity and consequent complications.

Upper Gastrointestinal Tract

Oropharyngeal manifestations of systemic sclerosis include xerostomia, microstomia, periodontal disease, and resorption of the mandibular condyles. The frenulum of the tongue may be shortened. Gastroesophageal reflux is associated with heartburn, regurgitation, and dysphagia; however, in some patients it can also be asymptomatic (Chapter 124). Reduced lower esophageal sphincter pressure frequently coexists with impaired esophageal clearance of refluxed gastric contents due to diminished motility in the distal esophagus.[9] Delayed gastric emptying further aggravates the problem.

Esophageal strictures and Barrett esophagus (Chapter 124) can complicate long-standing reflux. Hoarseness and chronic cough or throat clearing are common and may represent extraesophageal manifestations of reflux disease. Recurrent microaspiration of gastric contents may aggravate underlying interstitial lung disease. A distinct interstitial lung disease called centrilobular fibrosis, associated with esophageal dilation and chronic gastroesophageal reflux, is occasionally seen in systemic sclerosis.

Stomach

Gastroparesis and delayed gastric emptying manifest as early satiety, abdominal distention, and aggravated reflux symptoms.[10] Gastric vascular ectasia or "watermelon stomach" develops in 5% of patients and is more common in those with an anti-RNA polymerase III antibody. Patients with gastric vascular ectasia may have recurrent gastrointestinal bleeding and present with unexplained iron deficiency anemia.

Lower Gastrointestinal Tract

Impaired small bowel motility in systemic sclerosis can cause chronic diarrhea due to bacterial overgrowth. Ensuing fat and protein malabsorption, vitamin B_{12} and D deficiency, and malnutrition are associated with high mortality. Disturbed intestinal motor function can also cause recurrent intestinal pseudo-obstruction with acute abdominal pain, nausea, and vomiting. Colonic and anorectal involvement underlie constipation, rectal prolapse, and fecal incontinence. In late-stage disease, wide-mouth colonic sacculations can occur and cause perforation and bleeding. An occasional radiologic finding is pneumatosis cystoides intestinalis, which indicates air trapping in the bowel wall. Rupture of these lesions can cause pneumoperitoneum. Primary biliary cirrhosis can occur in patients with limited cutaneous systemic sclerosis.

Lung Involvement

Two major forms of lung involvement occur in systemic sclerosis: interstitial lung disease (Chapter 80) and pulmonary arterial hypertension (Chapter 69), which may coexist in many patients. Less frequent pulmonary manifestations include aspiration pneumonitis complicating gastroesophageal reflux, obliterative bronchiolitis, pleural reactions, restrictive ventilatory changes due to chest wall fibrosis, spontaneous pneumothorax, and drug-induced

lung toxicity. The risk of lung cancer, particularly bronchoalveolar carcinoma, is increased.

Interstitial Lung Disease

Interstitial lung disease (Chapter 80) in systemic sclerosis is common and can remain asymptomatic until it is quite advanced.[11] The most frequent presenting symptoms are exertional dyspnea,[12] fatigue, and reduced exercise tolerance. A chronic dry cough may be present. Physical examination may reveal "Velcro" crackles that are prominent at the lung bases.

Evidence of interstitial lung disease can be found in almost all patients with systemic sclerosis, is clinically significant in up to 50%, and may or may not progress. The most rapid progression generally occurs within the first 3 years of the onset of the disease, with patients losing greater than 100 mL/year in forced vital capacity.

Pulmonary Arterial Hypertension

Approximately 15% of systemic sclerosis patients develop pulmonary hypertension, defined as a mean resting pulmonary arterial pressure of 25 mm Hg or greater, with a pulmonary capillary wedge pressure of 15 mm Hg or less (Chapter 69). In the setting of systemic sclerosis, pulmonary hypertension can be an isolated abnormality, or it can coexist with interstitial lung disease.[13] Most patients have a progressive course, with development of right heart failure and increased mortality. Risk factors include limited cutaneous disease, older age of disease onset, severe Raynaud phenomenon, numerous cutaneous telangiectasias, and positivity for anticentromere, U1-RNP, U3-RNP (fibrillarin), Th/To, B23, or β_2-glycoprotein I autoantibodies.

The initial symptoms of pulmonary hypertension are exertional dyspnea and reduced exercise capacity, but early-stage disease is often clinically silent. With progression, angina, syncope, and symptoms and signs of right-sided heart failure manifest. Physical examination shows tachypnea, a prominent pulmonic S_2 heart sound, palpable right ventricular heave, elevated jugular venous pressure, and dependent edema.

Kidney Involvement

Scleroderma renal crisis, the most dreaded complication of systemic sclerosis, occurs in 10 to 15% of patients. It almost invariably occurs within 4 years of disease onset.[14] Vascular injury triggers obliterative vasculopathy, luminal narrowing in the renal arcuate arteries, a progressive reduction in renal blood flow, juxtaglomerular hyperplasia, and increased renin secretion, with further renal vasoconstriction resulting in a vicious cycle that culminates in accelerated hypertension and oliguric renal failure (Chapters 64 and 110). Patients characteristically present with abrupt onset of hypertension and progressive renal insufficiency, but the blood pressure remains normal or only modestly elevated in some cases. So-called normotensive renal crisis is associated with a poor outcome. Hypertensive encephalopathy and retinopathy, pericarditis, and arrhythmias may complicate scleroderma renal crisis. In many patients, oliguric renal failure develops over a period of weeks.

Risk factors for scleroderma renal crisis, beside early-stage (generally less than 4 years) disease, include rapidly progressive or extensive skin involvement with tendon friction rubs, Black race, male sex, and anti-RNA polymerases III positivity. In contrast, anticentromere positivity signals a low risk for scleroderma renal crisis. Pericardial effusion, new-onset anemia, and thrombocytopenia may be harbingers of impending scleroderma renal crisis, and recent corticosteroid use is associated with a more than 10-fold increased risk.

Abnormal renal function or proteinuria is detected in more than one third of patients with systemic sclerosis. However, such patients generally do not progress to end-stage renal disease.[15] Glomerulonephritis associated with lupus serologies or antineutrophil cytoplasmic antibody–positive renal vasculitis occurs.

Cardiac Involvement

Although frequently detected in systemic sclerosis using sensitive diagnostic tools, cardiac involvement is commonly silent.[16,17] Clinical cardiac involvement is more frequent in patients with diffuse cutaneous systemic sclerosis; it generally develops early in the course of the disease and represents a predictor of poor prognosis. The endocardium, myocardium, and pericardium may each be affected in isolation or in combination. Tachyarrhythmias, conduction abnormalities, valvular regurgitation, diastolic heart failure, and pericardial effusion can occur. Systemic and pulmonary arterial hypertension, as well as lung and renal involvement, also affect the heart. Myocarditis can develop in association with muscle inflammation. Pericardial effusion develops in more than 15% of patients but is not always clinically significant.

Musculoskeletal Complications

Carpal tunnel syndrome (Chapter 388) may be a presenting manifestation of systemic sclerosis. Joint mobility is progressively impaired, especially in the hands. Large joint contractures can be accompanied by audible or palpable tendon friction rubs that are caused by fibrosis and adhesion of the tendon sheaths and fascial planes at the affected joint. The presence of tendon friction rubs often signals aggressive disease. Frank joint inflammation is uncommon in systemic sclerosis; however, erosive polyarthritis in the hands can occur. Muscle weakness may be a sign of deconditioning, disuse atrophy, and malnutrition. Inflammatory myositis indistinguishable from idiopathic polymyositis (Chapter 248) may be seen, generally in early disease. A noninflammatory myopathy characterized by atrophy and fibrosis in the absence of elevated muscle enzyme levels is common in late disease. Bone resorption affects the distal tufts of terminal phalanges (acro-osteolysis), mandibular condyles, ribs, and distal clavicles.

Other Clinical Manifestations

In addition to microangiopathy, involvement of larger blood vessels (>100 μm) can occur in systemic sclerosis. Manifestations include occlusion of the digital and ulnar arteries, leading to ischemic ulcerations and even loss of digits or limbs. Epidemiologic studies indicate increased risk of coronary artery disease in patients with systemic sclerosis. Dry eyes and dry mouth are common in systemic sclerosis, but in contrast to primary Sjögren syndrome (Chapter 247), salivary gland biopsy in such cases may show fibrosis rather than focal lymphocytic infiltration. Hypothyroidism (Chapter 207) due to thyroid fibrosis is common and may be associated with antithyroid autoantibodies. Although the central nervous system is generally spared in systemic sclerosis, autonomic neuropathy, as well as a primarily sensory neuropathy of the trigeminal nerve due to fibrosis or vasculopathy, can occur. Pregnancy in women with active systemic sclerosis has been associated with an increased rate of adverse fetal outcomes. Furthermore, cardiopulmonary involvement might worsen during pregnancy, and scleroderma renal crisis can occur. In men, inability to attain or

maintain penile erection due to vascular insufficiency and fibrosis is frequent and may be the presenting disease manifestation.

Systemic Sclerosis and Cancer

Several studies indicate that patients with systemic sclerosis have an increased risk of cancer.[18] Lung cancer and esophageal adenocarcinoma typically occur in the setting of long-standing interstitial lung disease or gastroesophageal reflux disease, and chronic inflammation and tissue damage may be contributing factors. In contrast, systemic sclerosis-associated cancer of the breast, lung and ovaries, and lymphoma, tends to occur in close temporal association with the onset of systemic sclerosis and is often associated with anti-RNA polymerase III antibodies. In these cases, systemic sclerosis represents a paraneoplastic syndrome triggered by the antitumor immune response.

DIAGNOSIS

Induration in the fingers or proximally (associated with Raynaud phenomenon) and characteristic visceral organ manifestations are usually sufficient to establish the diagnosis of systemic sclerosis, although these features may be absent in early disease. Standardized criteria for the classification of systemic sclerosis show high degree of specificity and sensitivity (Table 246-3).

Rarely, full-thickness skin biopsy is required for excluding scleroderma mimics such as scleredema, scleromyxedema, or pansclerotic morphea (Table 246-4). Primary Raynaud (disease) is differentiated from systemic sclerosis by normal-appearing nailfold capillaries and absence of autoantibodies or other disease manifestations. Diagnosing systemic sclerosis can be difficult in the early stages of the disease because initial symptoms and findings are often nonspecific and can be mistaken for rheumatoid arthritis, systemic lupus erythematosus, inflammatory muscle disease, or undifferentiated connective tissue disease. Occasional patients whose systemic sclerosis presents with accelerated hypertension and renal failure or with gastrointestinal bleeding caused by watermelon stomach as the initial disease manifestation pose a diagnostic challenge.

Laboratory Features

Anemia is common in patients with systemic sclerosis and may reflect chronic inflammation, gastrointestinal bleeding from gastric vascular ectasia, erosive gastritis or chronic esophagitis, or folate and vitamin B_{12} deficiency due to small bowel bacterial overgrowth and malabsorption. Microangiopathic hemolytic anemia (Chapter 146) caused by mechanical trauma and red blood cell fragmentation in the damaged microvasculature is a laboratory hallmark of scleroderma renal crisis. In contrast to other rheumatic diseases, erythrocyte sedimentation rate and C-reactive protein generally show only modest elevation. Monitoring serum levels of prealbumin and vitamin K is useful in patients with small bowel bacterial overgrowth and malabsorption.

Circulating antinuclear autoantibodies are present in virtually all patients with systemic sclerosis and can be detected at, or even before, disease onset.[19] Other autoantibodies are specific for systemic sclerosis (see Table 246-1). Anticentromere antibodies are associated with pulmonary hypertension, whereas significant cardiac involvement, pulmonary fibrosis, or scleroderma renal crisis occurs only rarely in these patients. Topoisomerase-I antibody positivity is associated with pulmonary fibrosis and reduced survival. Antibodies to RNA polymerase III are associated with increased risk for scleroderma renal crisis. Uncharacterized autoantibodies showing a nucleolar pattern of immunofluorescence are generally associated with aggressive disease. Antibodies to β_2-glycoprotein I are not specific but in systemic sclerosis identify increased risk for critical ischemia.

Diagnosing Systemic Involvement

Esophageal Disease

On high-resolution computed tomography (HRCT) of the chest, the esophagus is dilated or patulous and shows intraluminal air. Endoscopy may show severe erosive esophagitis in patients with minimal reflux symptoms.

Gastric Disease

On endoscopy, parallel longitudinal mucosal folds resembling the stripes of a watermelon are seen in the gastric antrum. The histologic features of dilated thrombosed mucosal capillaries and fibromuscular dysplasia of the lamina propria represent the characteristic microangiopathy of systemic sclerosis.

Interstitial Lung Disease

Plain chest radiography is relatively insensitive for detection of early interstitial lung disease. In contrast, HRCT of the chest is highly sensitive (Chapter 72). Findings in systemic sclerosis include reticular interstitial opacities,

TABLE 246-3 THE AMERICAN COLLEGE OF RHEUMATOLOGY/EUROPEAN LEAGUE AGAINST RHEUMATISM CRITERIA FOR THE CLASSIFICATION OF SYSTEMIC SCLEROSIS

ITEM	SUB-ITEM(S)	WEIGHT/ SCORE*
Skin thickening of the fingers of both hands extending proximal to the metacarpophalangeal joints *(sufficient criterion)*	–	9
Skin thickening of the fingers *(only count the higher score)*	Puffy fingers Sclerodactyly of the fingers (distal to the metacarpophalangeal joints but proximal to the proximal interphalangeal joints)	2 4
Fingertip lesions *(only count the higher score)*	Digital tip ulcers Fingertip pitting scars	2 3
Telangiectasia	–	2
Abnormal nailfold capillaries	–	2
Pulmonary arterial hypertension and/or interstitial lung disease *(maximum score is 2)*	Pulmonary arterial hypertension Interstitial lung disease	2 2
Raynaud phenomenon	–	3
Systemic sclerosis-related autoantibodies (anticentromere, anti-topoisomerase I [anti-Scl-70], anti-RNA polymerase III) *(maximum score is 3)*	Anticentromere Anti-topoisomerase I Anti-RNA polymerase III	1 1 1

*The total score is determined by adding the maximum weight (score) in each category. Patients with a total score of 9 or higher are classified as having definite systemic sclerosis.

The criteria are not applicable to patients with skin thickening sparing the fingers or to patients who have a scleroderma-like disorder that better explains their manifestations (e.g., nephrogenic sclerosing fibrosis, generalized morphea, eosinophilic fasciitis, scleredema diabeticorum, scleromyxedema, porphyria, lichen sclerosis, graft-versus-host disease, diabetic cheiroarthropathy).

From van den Hoogen F, Khanna D, Fransen J, et al. 2013 classification criteria for systemic sclerosis: an American College of Rheumatology/European League Against Rheumatism collaborative initiative. *Arthritis Rheum*. 2013;65:2737-2747.

TABLE 246-4 CONDITIONS THAT MAY BE ASSOCIATED WITH SCLERODERMA-LIKE SKIN INDURATION

- Systemic sclerosis
  - Limited cutaneous systemic sclerosis
  - Diffuse cutaneous systemic sclerosis
- Localized scleroderma
  - Morphea (plaque, guttate, generalized)
  - Linear scleroderma, "coup de sabre"
- Pansclerotic morphea
- Paraneoplastic syndromes
- Scleredema and diabetic scleredema
- Scleromyxedema (papular mucinosis)
- Nephrogenic fibrosing syndrome (nephrogenic systemic fibrosis)
- Chronic graft-versus-host disease
- Diffuse fasciitis with eosinophilia (Shulman disease, eosinophilic fasciitis)
- Eosinophilia-myalgia syndrome
- Stiff skin syndrome
- Chemical exposure-associated scleroderma-like conditions
  - Vinyl chloride–induced disease, other solvents
  - Pentazocine-induced skin fibrosis
  - Other drug associations

predominantly in the lower lobe periphery, in isolation or in combination with ground-glass opacifications. Less common are mediastinal lymphadenopathy and honeycombing. The extent of lung disease on initial HRCT predicts progression of interstitial lung disease and may be useful when deciding the need for therapy. Bronchoalveolar lavage (Chapter 73) is occasionally needed to exclude infection, while lung biopsy is generally indicated only if lung cancer is suspected.

Pulmonary Hypertension

In patients who have pulmonary hypertension, the pulmonary artery systolic pressures as determined by screening Doppler echocardiography is greater than 40 mm Hg. Right heart catheterization is virtually always required to confirm the diagnosis of pulmonary hypertension, assess its severity, and evaluate ventricular function.

Scleroderma Renal Crisis and Nephropathy

In systemic sclerosis-associated renal disease, the urinalysis usually shows only mild proteinuria, granular casts, and microscopic hematuria. Thrombocytopenia and microangiopathic hemolysis with fragmented red blood cells can sometimes erroneously lead to the diagnosis of thrombotic thrombocytopenic purpura or hemolytic-uremic syndrome (Chapter 158). Kidney biopsy, which is occasionally required for diagnosis and prognosis, can show chronic changes including reduplication of elastic fibers, sclerosed glomeruli, tubular atrophy, and interstitial fibrosis. However, the characteristic arteriolar intimal and medial proliferation and luminal narrowing are indistinguishable from the changes of accelerated hypertension.

Cardiac Involvement

Conventional echocardiography has a low sensitivity for detecting systemic sclerosis-associated heart involvement. In contrast, tissue Doppler echocardiography, single-photon emission computed tomography, and especially cardiac magnetic resonance imaging (cMRI) commonly reveal myocardial abnormalities in systemic sclerosis. Characteristic findings include abnormal ventricular relaxation and reversible perfusion defects. An elevated serum NT-pro-BNP in systemic sclerosis is a sensitive marker for increased pulmonary artery pressure but may also indicate primary cardiac involvement.

TREATMENT AND PREVENTION

Because of the marked patient-to-patient variability in clinical presentation, a comprehensive baseline evaluation is paramount. Optimal patient management should include prompt diagnosis, accurate classification and risk stratification, early recognition and assessment of organ-based complications, and long-term monitoring of progression, disease activity, and response to therapy. Management of complications should be proactive, with regular screening and initiation of appropriate intervention at the earliest possible opportunity. Given the multisystem nature of systemic sclerosis, an integrated team approach, typically at specialized medical centers where relevant expertise is available, is optimal.

Immunosuppressive agents that are highly effective in other connective tissue diseases have shown modest or no benefit in systemic sclerosis. Corticosteroids alleviate stiffness, fatigue, and aching in early-stage disease, but do not slow disease progression and are associated with an increased risk for scleroderma renal crisis. Therefore corticosteroids should be avoided if possible; when absolutely necessary, they should be given at the lowest dose possible and for brief periods only.

Skin Care

Skin involvement in early systemic sclerosis is inflammatory, and symptoms may respond to systemic antihistamines or short-term low-dose corticosteroid treatment. Skin dryness can be managed with the use of hydrophilic ointments and emollient bath oils. Fingertip ulcerations should be protected by occlusive dressing to promote healing and prevent infection. Infected skin ulcers are treated with topical or oral antibiotics and may necessitate surgical débridement. Because of the increased risk for scleroderma renal crisis, blood pressure should be carefully monitored.

Mycophenolate (up to 3000 mg/d), cyclophosphamide (up to 2 mg/kg/d), methotrexate (15 mg/week), and rituximab (1000 mg IV on days 0 and day 15, then repeated every 6 months) have been associated with modest improvement in skin induration in early-stage systemic sclerosis. Some data support the use of abatacept, tofacitinib, intravenous immunoglobulin, and extracorporeal photopheresis for the treatment of some patients with systemic sclerosis. No medical therapy has been shown to be effective in preventing soft tissue calcification or in promoting its dissolution, and surgical therapy and lithotripsy are only occasionally effective.

Autologous hematopoietic stem cell transplantation is emerging as a therapeutic option in carefully screened patients whose severe systemic sclerosis fails to respond to other treatments (Chapter 163). This intervention can improve skin, disease, pulmonary disease, and long-term event-free survival, although it is associated with a treatment-related mortality of up to 6% at 72 months.[A1]

Interstitial Lung Disease

The optimal management of patients with subclinical interstitial lung disease is currently uncertain. Patients with symptomatic interstitial lung disease or extensive pulmonary function or radiologic abnormalities should be treated with mycophenolate (up to 3000 mg/d).[A2] Cyclophosphamide (up to 2 mg/kg/d) also can slow the progression of symptomatic interstitial lung disease in early systemic sclerosis,[A3] but these benefits are short-lived. Rituximab (given IV at 1000 mg on days 0 and 15 and then every 6 months) has shown some benefit in improving skin involvement and stabilizing lung function,[A4] but it has not been evaluated in long-term randomized trials.

If lung disease progresses despite 3 to 6 months of such treatment, the antifibrotic drug nintedanib (150 mg bid), or tocilizumab (162 mg subcutaneously weekly) should be added.[20,21] Nintedanib slows the rate of decline in the forced vital capacity of patients with systemic sclerosis-associated interstitial lung disease by about 45%, although it does not alter other disease manifestations.[A5,A6] Tocilizumab also can significantly slow the loss of lung function in patients with early disease.[A7,A8]

Gastrointestinal Complications

Because even significant gastroesophageal reflux may be asymptomatic, all patients with systemic sclerosis should be treated for this complication (Chapter 124). Proton pump inhibitors (Table 124-1) may need to be given in relatively high doses and for prolonged periods. Patients should be instructed to elevate the head of the bed and eat frequent small meals. Recurrent gastrointestinal bleeding due to gastric vascular ectasia can be treated with laser or argon plasma photocoagulation. Bacterial overgrowth (Chapter 126) is treated with antibiotics. In patients with malnutrition but intact small bowel function, enteral nutrition (Chapter 198) can be effective. Refractory hypomotility of the small bowel may respond to subcutaneous octreotide injections (Chapter 122). Anorectal complications may respond to sacral neuromodulation (Chapter 131).

Vascular Disease

The goal of vascular therapy in systemic sclerosis is to reduce the frequency and duration of vasospastic episodes, prevent ischemic complications, and enhance their healing, and slow the progression of obliterative vasculopathy.[22] Patients should dress warmly, minimize cold exposure, and avoid cigarette smoking or drugs that could precipitate or exacerbate vasospastic episodes. Calcium-channel blockers such as nifedipine and diltiazem (Chapter 66) are used commonly for Raynaud phenomenon but show only moderate benefit, and their use is often limited by side effects. Angiotensin II receptor blockers such as losartan (up to 50 mg/day) are effective and generally well tolerated. Patients with severe Raynaud phenomenon and ischemic digital ulcers may require 5-phosphodiesterase inhibitors (e.g., sildenafil 2 mg three times daily), intradigital botulinum toxin injections, bosentan (62.5 mg twice daily), local sympathetic blockade, or intravenous prostaglandins. Low-dose aspirin (81 mg daily) and dipyridamole (25 mg three times daily) prevent platelet activation and may have a role as adjunctive agents in treating Raynaud phenomenon, but they must be used with caution in light of the risk of bleeding from gastric vascular ectasia lesions.

The endothelin-1 receptor antagonist bosentan (62.5 mg twice daily) reduces development of new ischemic ulcers, and sildenafil (20 mg three times daily) may promote ulcer healing.[A9] Patients with ischemic digital ulcerations may require surgical débridement, especially if necrotic tissue is present. Empirical long-term therapy with statins and antioxidants may slow the progression of vascular damage.

Pulmonary Arterial Hypertension

All patients with systemic sclerosis should be screened for pulmonary hypertension at initial evaluation, and those high-risk patients (see Table 69-2) should be screened on a yearly basis. Rituximab (1000 mg IV on days 0 and 15, then repeated every 6 months) has shown promising results.[A10] Otherwise, treatment is as for symptomatic pulmonary hypertension (see Fig. 69-6) in general, beginning with an endothelin-1 receptor antagonist or a 5-phosphodiesterase inhibitor. If the clinical response is inadequate, 5-phosphodiesterase inhibitors may be used in combination with endothelin-1 receptor antagonists. Prostacyclin analogs can be administered intravenously, by continuous subcutaneous infusion, or by frequent inhalations (see Chapter 69). Lung transplantation remains an option for selected patients with systemic sclerosis–associated pulmonary hypertension or interstitial lung disease who fail medical therapy.

Scleroderma Renal Crisis

Early recognition of impending or early scleroderma renal crisis is essential. In patients presenting with renal crisis, hospitalization and prompt initiation of short-acting angiotensin converting enzyme (ACE) inhibitors in escalating doses

is essential. The goal is to achieve adequate blood pressure control before the onset of renal failure.

Because patients with early-stage systemic sclerosis and progressive skin involvement are at highest risk, they should be instructed to monitor their blood pressure daily and report significant alterations immediately. Corticosteroids should be used only when absolutely necessary and at the lowest possible doses. There is no evidence that prophylactic use of ACE inhibitors can prevent the development of scleroderma renal crisis or ameliorate its severity.

PROGNOSIS

Patients with diffuse cutaneous systemic sclerosis have a more rapidly progressive disease course, greater internal organ involvement, and generally worse prognosis compared with those with limited cutaneous systemic sclerosis. However, the outcome of the disease in an individual patients can be difficult to predict.

Early inflammatory symptoms such as fatigue, edema, arthralgia, and pruritus commonly subside. Skin thickening typically reaches a plateau, followed by slow regression, which characteristically occurs in an order that is the reverse of initial involvement, with softening on the trunk followed by proximal and finally the distal extremities. Sclerodactyly, finger contractures, and microstomia generally fail to resolve. Relapse or recurrence of skin thickening may occur with tapering or discontinuation of therapy. Visceral organ involvement develops and shows most rapid progression during the initial 2 to 4 years of the disease. New organ involvement rarely occurs once the skin involvement has reached a plateau. Similarly, scleroderma renal crisis almost invariably occurs within the first 4 years of disease. In patients with limited cutaneous systemic sclerosis, Raynaud phenomenon may precede other disease manifestations by years or even decades. In these patients, Raynaud, reflux, and calcinosis generally persist, and visceral organ complications such as pulmonary hypertension and primary biliary cirrhosis may develop late in the course of the disease.

Age- and gender-adjusted standardized mortality ratios (SMRs) in patients with systemic sclerosis have ranged from 1.05 to 5.40 across studies, but an overall SMR of 2.72 higher than in the general population.[23] The 10-year survival rate is 55% for patients with diffuse cutaneous systemic sclerosis and 75% for patients with limited cutaneous systemic sclerosis. Survival correlates with the extent of skin involvement, which represents a surrogate for visceral organ involvement. The leading causes of death are pulmonary fibrosis, pulmonary hypertension, renal and severe gastrointestinal involvement, and cardiac disease. Markers of poor prognosis include male sex, Black race, older age at disease onset, low body mass index, extensive skin thickening with truncal involvement, and evidence of significant or progressive visceral organ involvement. Autoantibodies to topoisomerase-I or absence of anticentromere antibodies are markers of poor prognosis. In one study, systemic sclerosis patients who had extensive skin involvement, vital capacity less than 55% of predicted, significant gastrointestinal involvement, and clinically evident cardiac involvement or scleroderma renal crisis had a less than 40% 10-year survival.

The severity of pulmonary hypertension in systemic sclerosis is correlated with mortality. Patients with a mean pulmonary artery pressure of 45 mm Hg or higher have about a 33% 3-year survival rate.

In scleroderma renal crisis, therapy with ACE inhibitors has had a dramatic effect on survival, increasing from less than 10% at 1 year in the pre-ACE inhibitor era to better than 70% 3-year survival at the present time. Despite timely intervention, however, more than 50% of patients with scleroderma renal crisis will require renal replacement therapy, although some ultimately recover sufficient renal function to be able to discontinue hemodialysis. Oliguria or a serum creatinine higher than 3 mg/dL at presentation predicts poor outcome. Kidney transplantation is appropriate for patients unable to discontinue dialysis after 2 years. Survival with renal transplantation in systemic sclerosis is comparable to that in other connective tissue diseases, and recurrence of scleroderma renal crisis in the kidney graft is rare.

OTHER SCLEROTIC DISEASES

MIXED CONNECTIVE TISSUE DISORDER

Mixed connective tissue disorder (MCTD) is an overlap syndrome that is characterized by features of systemic lupus erythematosus, systemic sclerosis, and myositis, all occurring in the same patient.[24] In the early phase, most patients have Raynaud phenomenon in association with edema of the hands and evidence of inflammatory muscle disease. Over time, these patients sequentially manifest other features of connective tissue diseases, including pericarditis, esophageal dysmotility, sclerodactyly, neuropathy, and pulmonary arterial hypertension. Erosive arthritis does not occur. However, some patients develop acute renal involvement similar to scleroderma renal crisis. In the early stage of this disorder, it can be difficult to predict whether the patient will progress to develop a distinct connective tissue disease such as systemic sclerosis or systemic lupus erythematosus.[25] A diagnostic hallmark of mixed connective tissue disorder is the presence of autoantibody specificity against U1-ribonuclear protein (U1-RNP), often at very high titer.

TREATMENT AND PROGNOSIS

The treatment of mixed connective tissue is generally symptomatic, including nonsteroidal anti-inflammatory agents (Table 26-4), with glucocorticoids (e.g., prednisone up to 1 mg/kg/day) and hydroxychloroquine (200 mg daily) for more severe disease in specific affected organs. Patients with mixed connective tissue disorder generally have a better prognosis than those with systemic sclerosis.

LOCALIZED SCLERODERMAS

Localized scleroderma refers to a family of generally benign skin conditions characterized by discreet areas of skin induration in the absence of Raynaud phenomenon or of significant systemic involvement.[26] Lesional skin is discolored and indurated and histologically may be indistinguishable from systemic sclerosis. Localized scleroderma has multiple distinct forms. When it occurs as single or multiple solitary patches of induration, it is called morphea. When these patches coalesce, the condition is called generalized morphea. The lesions are generally asymmetric in distribution and spare the digits. Induration may follow in a linear distribution, most commonly on the lower extremities (linear scleroderma). In children, linear scleroderma can be complicated by growth retardation and joint contractures.

In adults with localized scleroderma, methotrexate (15 mg per week), mycophenolate (up to 1500 mg twice daily), topical calcipotriene (0.005% applied twice daily), and ultraviolet phototherapy have shown benefit. A rare but severe variant with extensive, disabling, and treatment-resistant chronic skin induration, but lacking significant internal organ involvement, is called pansclerotic morphea.

Immunoglobulin (Ig)G4–related disease is discussed in Chapter 254.

NEPHROGENIC SYSTEMIC FIBROSIS

Nephrogenic systemic fibrosis is a complication of exposure to gadolinium-containing MRI contrast agents in patients with acute kidney injury (Chapter 106), renal insufficiency, or stage 4 or 5 chronic kidney disease (Chapter 116), with an incidence in such patients of less than 0.07%.[27] With newer contrast agents[28] and current protocols that screen for renal function before administering gadolinium, this complication has essentially disappeared. The cutaneous manifestations of nephrogenic systemic fibrosis share histopathologic and clinical features with other scleroderma-spectrum disorders. Histological hallmarks include cutaneous fibrosis with mucin deposition and accumulation of spindle-shaped CD34-positive cells. The clinical hallmark of nephrogenic systemic fibrosis is thickening and "woody" tightness of skin over the lower and, less commonly, upper extremities and contractures at large joints. Anecdotal reports describe treatment with phototherapy, imatinib mesylate, and immunosuppressive agents. However, in most patients with nephrogenic systemic fibrosis, the induration is resistant to therapy and leads to progressive induration, joint contractures, and reduced mobility. Prevention centers on avoiding the use of gadolinium in patients with renal insufficiency.

RETROPERITONEAL FIBROSIS

Retroperitoneal fibrosis, which is a rare primary or secondary fibro-inflammatory condition, involves the adventitia and periaortic tissues surrounding the infrarenal portion of the abdominal aorta, often the iliac arteries, and sometimes the thoracic aorta.[29] The process can encase the ureters and other abdominal organs. The disease has an estimated prevalence of 1.4 per 100,000 population. In the idiopathic form, the mean age at onset is 55 to 60 years, and about two-thirds of cases are in men.

About 50% of cases of primary retroperitoneal fibrosis are associated with immunoglobulin (Ig) G4-related disease (Chapter 254).[30] Most of the remainder are apparently idiopathic, but some cases may be secondary to tumors (e.g.,

carcinoid [Chapter 213], lymphomas [Chapter 171], sarcomas [Chapter 187], and retroperitoneal metastases from solid tumors), autoimmune disorders (e.g., Hashimoto thyroiditis [Chapter 207], rheumatoid arthritis [Chapter 243], systemic vasculitis [Chapter 249], systemic lupus erythematosus [Chapter 245], and Erdheim-Chester disease [Chapter 155]), infections (e.g., tuberculosis [Chapter 299]), drugs (e.g., ergot alkaloids, dopamine agonists, etanercept, and infliximab), radiotherapy (e.g., for testicular, colon, or pancreatic cancer), other fibrotic conditions (e.g., sclerosing cholangitis [Chapter 141], autoimmune pancreatitis [Chapter 130], fibrosing mediastinitis [Chapter 86]), or retroperitoneal hemorrhage. Risk factors for the idiopathic form include asbestos exposure and cigarette smoking, with the combination of the two further increasing the risk.

The pathogenesis of retroperitoneal fibrosis is not well understood, but an association with HLA-DRB1*03 suggests an autoimmune genetic component. The pathobiology is characterized by the local production of IL-6 and Th2 cytokines as well as the accumulation of CD4+ T cells, B cells, myofibroblasts, and a fibrotic extracellular matrix composed of type 1 collagen fibers. Fibrosis and inflammation often encircle small retroperitoneal blood vessels as well as the aorta, iliac arteries, and inferior vena cava.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common clinical symptoms are low back, flank, or testicular pain and vague constitutional symptoms. Other common clinical presentations include anorexia, nausea, and lower extremity edema. Laboratory evaluation typically shows anemia, elevated levels of acute phase reactants, and impaired renal function. A positive antinuclear antibody (ANA) is seen in a majority of idiopathic cases. Levels of IgG4 are commonly elevated in both IgG4-related disease and other forms of retroperitoneal fibrosis, as well as in mimics such as Castleman disease (Chapter 171) and Erdheim-Chester disease (Chapter 155). Patients also should have studies of renal, thyroid, and liver function, as well as a serum amylase level.

Medial deviation of the ureters often leads to obstruction. Obstructive uropathy is associated with hydronephrosis and acute kidney injury. Vascular involvement can include inflammatory abdominal aortic aneurysms. The diagnosis is often made by a contrast-enhanced computed tomographic (CT) scan or magnetic resonance imaging (MRI) showing homogeneous plaque surrounding the anterolateral abdominal aortic wall, typically encircling the common iliac arteries and inferior vena cava.[31] Retroperitoneal biopsy sometimes may be indicated to exclude secondary causes, including tumors, tuberculosis, and conditions such as pelvic actinomycosis (Chapter 304) that can mimic retroperitoneal fibrosis, especially in women who have used an intrauterine device.

TREATMENT AND PROGNOSIS

For primary or idiopathic retroperitoneal fibrosis, first-line treatment is prednisone (0.75 to 1 mg/kg gradually tapered over 6 to 9 months to 5 to 7.5 mg per day). For severe ureteral obstruction or obstruction that does not respond to prednisone therapy, ureteral stenting or a nephrostomy tube is indicated, and surgical ureterolysis may be required for refractory cases.[32] Immunomodulatory therapies, including mycophenolate mofetil, cyclophosphamide, rituximab, methotrexate, and tamoxifen, have been used under expert supervision in combination with prednisone in refractory cases, or as steroid-sparing therapies. For secondary causes, cause-specific treatment may often be accompanied by local ureteral procedures.

About 75 to 95% of patients with retroperitoneal fibrosis respond to steroid therapy, but the relapse rate is about 70%. About one third of patients develop chronic renal insufficiency, but end-stage renal disease is rare. For secondary causes, prognosis is related to the underlying disease.

247 SJÖGREN SYNDROME

E. WILLIAM ST. CLAIR

DEFINITION

Sjögren syndrome is a systemic autoimmune disease with glandular and extraglandular manifestations.[1] Its cardinal glandular features are keratoconjunctivitis sicca, or dry eyes, and xerostomia, or dry mouth, otherwise known as the sicca complex.

Sjögren syndrome can be primary or secondary. It is primary when the sicca complex occurs in the absence of another rheumatologic disease. The term secondary refers to the presence of keratoconjunctivitis sicca or xerostomia in association with another rheumatologic disease, such as rheumatoid arthritis (Chapter 243), systemic lupus erythematosus (Chapter 245), or systemic sclerosis (Chapter 246).

EPIDEMIOLOGY

Primary Sjögren syndrome has a prevalence of 0.6 to 1.5%. It is predominantly a disease of women, with a female:male ratio of approximately 10:1. The peak onset is in the fifth and sixth decades of life, but the disease may begin in childhood through the eighth decade.

The secondary form occurs most commonly in the setting of rheumatoid arthritis (Chapter 243), with a prevalence of 30 to 50%. Keratoconjunctivitis sicca and xerostomia are also present in 15 to 20% of patients with systemic sclerosis (Chapter 246) and 10 to 15% of patients with systemic lupus erythematosus (Chapter 245).

PATHOBIOLOGY

Genetics

A genetic contribution to the risk for primary Sjögren syndrome is supported by familial clustering of cases and aggregation of cases in families with other autoimmune diseases. First-degree relatives of patients with Sjögren syndrome have a higher prevalence of rheumatoid arthritis, systemic lupus erythematosus, inflammatory myopathy, type 1 diabetes mellitus, and multiple sclerosis. Nevertheless, most cases of primary Sjögren syndrome occur sporadically in the absence of a family history of autoimmune disease.

Most of the genetic susceptibility is conferred by polymorphisms in the human leukocyte antigen (HLA) loci, with the strongest effects from the HLA-DR and HLA-DQ class II HLA molecules.[2] Primary Sjögren syndrome is associated with HLA class II alleles DRB1*03:01, DQA1*05:01, and DQB1*02:01. Other genetic susceptibility loci identified in genome-wide association studies include those linked to type I interferon signaling (*IRF5*, *IL12A*, and *STAT4*, *OAS1*), B-cell development and activation (*BLK*, *EBF1*), nuclear factor kappa β (NF-κB) signaling (*TNIP1*, *TNFAIP3*), and lymphocyte trafficking (*CXCR5*).

carcinoid [Chapter 213], lymphomas [Chapter 171], sarcomas [Chapter 187], and retroperitoneal metastases from solid tumors), autoimmune disorders (e.g., Hashimoto thyroiditis [Chapter 207], rheumatoid arthritis [Chapter 243], systemic vasculitis [Chapter 249], systemic lupus erythematosus [Chapter 245], and Erdheim-Chester disease [Chapter 155]), infections (e.g., tuberculosis [Chapter 299]), drugs (e.g., ergot alkaloids, dopamine agonists, etanercept, and infliximab), radiotherapy (e.g., for testicular, colon, or pancreatic cancer), other fibrotic conditions (e.g., sclerosing cholangitis [Chapter 141], autoimmune pancreatitis [Chapter 130], fibrosing mediastinitis [Chapter 86]), or retroperitoneal hemorrhage. Risk factors for the idiopathic form include asbestos exposure and cigarette smoking, with the combination of the two further increasing the risk.

The pathogenesis of retroperitoneal fibrosis is not well understood, but an association with HLA-DRB1*03 suggests an autoimmune genetic component. The pathobiology is characterized by the local production of IL-6 and Th2 cytokines as well as the accumulation of CD4+ T cells, B cells, myofibroblasts, and a fibrotic extracellular matrix composed of type 1 collagen fibers. Fibrosis and inflammation often encircle small retroperitoneal blood vessels as well as the aorta, iliac arteries, and inferior vena cava.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common clinical symptoms are low back, flank, or testicular pain and vague constitutional symptoms. Other common clinical presentations include anorexia, nausea, and lower extremity edema. Laboratory evaluation typically shows anemia, elevated levels of acute phase reactants, and impaired renal function. A positive antinuclear antibody (ANA) is seen in a majority of idiopathic cases. Levels of IgG4 are commonly elevated in both IgG4-related disease and other forms of retroperitoneal fibrosis, as well as in mimics such as Castleman disease (Chapter 171) and Erdheim-Chester disease (Chapter 155). Patients also should have studies of renal, thyroid, and liver function, as well as a serum amylase level.

Medial deviation of the ureters often leads to obstruction. Obstructive uropathy is associated with hydronephrosis and acute kidney injury. Vascular involvement can include inflammatory abdominal aortic aneurysms. The diagnosis is often made by a contrast-enhanced computed tomographic (CT) scan or magnetic resonance imaging (MRI) showing homogeneous plaque surrounding the anterolateral abdominal aortic wall, typically encircling the common iliac arteries and inferior vena cava.[31] Retroperitoneal biopsy sometimes may be indicated to exclude secondary causes, including tumors, tuberculosis, and conditions such as pelvic actinomycosis (Chapter 304) that can mimic retroperitoneal fibrosis, especially in women who have used an intrauterine device.

TREATMENT AND PROGNOSIS

For primary or idiopathic retroperitoneal fibrosis, first-line treatment is prednisone (0.75 to 1 mg/kg gradually tapered over 6 to 9 months to 5 to 7.5 mg per day). For severe ureteral obstruction or obstruction that does not respond to prednisone therapy, ureteral stenting or a nephrostomy tube is indicated, and surgical ureterolysis may be required for refractory cases.[32] Immunomodulatory therapies, including mycophenolate mofetil, cyclophosphamide, rituximab, methotrexate, and tamoxifen, have been used under expert supervision in combination with prednisone in refractory cases, or as steroid-sparing therapies. For secondary causes, cause-specific treatment may often be accompanied by local ureteral procedures.

About 75 to 95% of patients with retroperitoneal fibrosis respond to steroid therapy, but the relapse rate is about 70%. About one third of patients develop chronic renal insufficiency, but end-stage renal disease is rare. For secondary causes, prognosis is related to the underlying disease.

247 SJÖGREN SYNDROME

E. WILLIAM ST. CLAIR

DEFINITION

Sjögren syndrome is a systemic autoimmune disease with glandular and extraglandular manifestations.[1] Its cardinal glandular features are keratoconjunctivitis sicca, or dry eyes, and xerostomia, or dry mouth, otherwise known as the sicca complex.

Sjögren syndrome can be primary or secondary. It is primary when the sicca complex occurs in the absence of another rheumatologic disease. The term secondary refers to the presence of keratoconjunctivitis sicca or xerostomia in association with another rheumatologic disease, such as rheumatoid arthritis (Chapter 243), systemic lupus erythematosus (Chapter 245), or systemic sclerosis (Chapter 246).

EPIDEMIOLOGY

Primary Sjögren syndrome has a prevalence of 0.6 to 1.5%. It is predominantly a disease of women, with a female:male ratio of approximately 10:1. The peak onset is in the fifth and sixth decades of life, but the disease may begin in childhood through the eighth decade.

The secondary form occurs most commonly in the setting of rheumatoid arthritis (Chapter 243), with a prevalence of 30 to 50%. Keratoconjunctivitis sicca and xerostomia are also present in 15 to 20% of patients with systemic sclerosis (Chapter 246) and 10 to 15% of patients with systemic lupus erythematosus (Chapter 245).

PATHOBIOLOGY

Genetics

A genetic contribution to the risk for primary Sjögren syndrome is supported by familial clustering of cases and aggregation of cases in families with other autoimmune diseases. First-degree relatives of patients with Sjögren syndrome have a higher prevalence of rheumatoid arthritis, systemic lupus erythematosus, inflammatory myopathy, type 1 diabetes mellitus, and multiple sclerosis. Nevertheless, most cases of primary Sjögren syndrome occur sporadically in the absence of a family history of autoimmune disease.

Most of the genetic susceptibility is conferred by polymorphisms in the human leukocyte antigen (HLA) loci, with the strongest effects from the HLA-DR and HLA-DQ class II HLA molecules.[2] Primary Sjögren syndrome is associated with HLA class II alleles DRB1*03:01, DQA1*05:01, and DQB1*02:01. Other genetic susceptibility loci identified in genome-wide association studies include those linked to type I interferon signaling (*IRF5*, *IL12A*, and *STAT4*, *OAS1*), B-cell development and activation (*BLK*, *EBF1*), nuclear factor kappa β (NF-κB) signaling (*TNIP1*, *TNFAIP3*), and lymphocyte trafficking (*CXCR5*).

Immune Mechanisms of Disease

The immunologic mechanisms of primary Sjögren syndrome involve dysregulation of both adaptive and innate immune pathways that drive a chronic inflammatory response in the target tissues. In the salivary glands, foci of mononuclear cells infiltrate areas of preserved acinar gland architecture (E-Fig. 247-1). Immunohistochemical analyses of these infiltrates show a predominance of $CD4^+$ T lymphocytes and B lymphocytes, which together represent about 90% of the immune cells.[3] The other immune cells comprising the infiltrate consist of $CD8^+$ T lymphocytes, $CD56^+$ natural killer cells, $FoxP3^+$ T regulatory lymphocytes, macrophages, and myeloid and plasmacytoid dendritic cells. T and B lymphocytes tend to coalesce around ducts and blood vessels and, in more inflammatory lesions, form germinal center-like structures.

The salivary gland tissue is flooded with pro-inflammatory chemokines and cytokines. Activated epithelial cells secrete *CXCL12*, *CXCL13*, and *CCL2*, as well as other mediators that cooperate to recruit, retain, and promote the survival of B lymphocytes.[4] Macrophages and myeloid dendritic cells secrete tumor necrosis factor (TNF), IL-6, IL-12, and IL-18 in abundance. There is overexpression of type I interferon-inducible genes in both the salivary gland tissue and the peripheral blood.

B lymphocytes are the precursors of antibody-secreting cells, which produce the autoantibodies and lead to the hypergammaglobulinemia, cryoglobulinemia, and elevated levels of circulating immune complexes.[5] Most B lymphocytes in salivary gland tissue express a memory phenotype and immunoglobulin (Ig) domains encoded by somatically hypermutated immunoglobulin V region genes, with structural characteristics typical of an antigen-driven response. The survival of B lymphocytes is enhanced by the upregulation of B-cell activating factor, which is produced mainly by plasmacytoid dendritic cells, as well as epithelial cells and macrophages, and is inducible by type I interferon.

Antibodies to SSA (Ro) and SSB (La) antigens, while diagnostic and prognostic biomarkers, are not known to be directly involved in causing the disease. In contrast, antibodies to the muscarinic receptor 3 (MR3) may suppress glandular function. Acetylcholine binds to the MR3 receptor expressed on the surface of lacrimal and salivary acinar glands, where it stimulates tear and salivary flow.

A prominent feature of primary Sjögren syndrome is the increased risk of lymphoma, usually a marginal zone lymphoma (Chapter 171). The evolution of lymphoma in this setting is initiated by a polyclonal B lymphocyte response, with expansion of oligoclonal and monoclonal B lymphocyte populations followed by clonal transformation.[6] The mechanisms underlying malignant transformation appear to depend on the activation of NF-κB. The A20 protein is a critical gatekeeper and inhibitor of the NF-κB pathway. The *TNFAIP3* gene encoding the A20 protein is somatically deleted in some cases of marginal zone B-cell lymphoma without autoimmunity, whereas the risk for lymphoma in patients with primary Sjögren syndrome is associated with a single nucleotide polymorphism in the coding region of the *TNFAIP3* gene. This polymorphism leads to a functional abnormality in the A20 protein, which in turn, promotes overactivation of the NF-κB pathway and loss of an important escape mechanism in lymphomagenesis.

Pathobiology

A dry eye may result from a deficiency in any of the three layers of the tear film: the outer lipid layer produced by the meibomian glands, the middle aqueous layer secreted by the lacrimal glands, and the inner mucous layer derived from the conjunctival goblet cells. Dry mouth and its complications are the product of reduced salivary flow, as well as changes in the concentrations of salivary electrolytes and proteins. Fatigue, which is the most prevalent extraglandular symptom, often has a multifactorial basis and may arise from disease-related mechanisms, depression, anxiety, fibromyalgia, sleep disturbance, or medication side effects.

CLINICAL MANIFESTATIONS

The severity of symptoms in Sjögren disease can be assessed in a number of domains: glandular, constitutional, cutaneous, respiratory, renal, articular, muscular, peripheral nervous system, central nervous system, hematologic, lymphadenopathic, and biologic.[7]

Glandular (Sicca) Features

Glandular hypofunction leads to dry eyes and dry mouth, as well as dryness of other epithelial surfaces, including the skin and the mucosa of the nasopharynx, larynx, airways, esophagus, and vagina. The hallmark symptoms of dry eye are the sensation of an ocular foreign body (gritty or sandy feeling), redness, burning, photophobia, and blurred vision.

Symptoms of dry mouth include difficulty with speaking, chewing, and swallowing. Examination often reveals a dry buccal mucosa, with diminished sublingual salivary pooling, sticky and thickened saliva, and a dry fissured tongue. Patients with xerostomia are prone to cavities and cracked teeth, as well as oral candidiasis (atrophic variant) that is often accompanied by angular cheilitis.

Some but not all patients experience swelling of the parotid or submandibular glands. Sudden onset of unilateral salivary gland swelling from transient duct obstruction usually resolves within a few days. Swelling of the parotid or submandibular glands may also persist or wax and wane over the disease course. Glands with palpably firm or hard nodules, especially those that are increasing in size, may signify a lymphoma.

Extraglandular Features

Extraglandular manifestations of primary Sjögren syndrome occur in approximately 50% of patients with this disease, although only about 15% develop serious organ system involvement. Fatigue is the most common extraglandular symptom. Raynaud syndrome (Chapter 66) occurs in up to one-third of patients and may precede the onset of sicca symptoms by several years.

Polyarthralgia/polyarthritis occurs commonly in Sjögren syndrome and may precede its diagnosis. The joints most frequently affected are the wrists, hands, ankles, and feet. The degree of synovial inflammation is generally much less severe than in rheumatoid arthritis and does not lead to erosive joint damage.

The types of skin rash are varied and include annular erythema, subacute cutaneous lupus erythematosus, and cutaneous vasculitis. Annular erythema appears in different forms: a donut-ring erythema with an elevated border, a polycyclic-like erythema with marginal scaling, and a papular lesion resembling an insect bite. These lesions are not photosensitive and resolve without residual hyperpigmentation. Subacute cutaneous lupus erythematosus is associated with photosensitivity, the presence of anti-Ro/SSA antibodies, and papulosquamous lesions with scaling or with annular, polycyclic lesions with marginal scale and central clearing.

Cutaneous vasculitis may present as palpable purpura, ulcers, erythematous papules and macules, and urticarial vasculitis. Urticarial vasculitis may be distinguished from allergic urticaria by the persistence of these lesions at a single location for more than 24 hours and by their tendency to leave a bruise. Nonpalpable purpura may occur in patients with high levels of serum immunoglobulins.

Lung involvement in primary Sjögren syndrome most frequently takes the form of small airways disease or interstitial lung disease (Chapter 80),[8] especially nonspecific interstitial pneumonitis and usual interstitial pneumonitis. About 5 to 10% of patients develop clinically significant type 1 distal renal tubular acidosis (Chapter 104), tubular interstitial nephritis (Chapter 108), and glomerulonephritis (Chapter 107).[9] Type 1 renal tubular acidosis increases the risk for nephrolithiasis (Chapter 111). Immune complex–mediated glomerular diseases include mesangial proliferative, membranous, membranoproliferative, and focal crescentic forms. Membranoproliferative glomerulonephritis is the form most commonly associated with cryoglobulinemic vasculitis.

A minority of patients develop nervous system deficits, mostly distal sensory and sensorimotor peripheral neuropathies (Chapter 388).[10] A sensorimotor neuropathy usually presents in the limbs with painful, length-dependent dysesthesias, and only rarely progresses to cause distal extremity weakness. Pure sensory small fiber neuropathies often cause painful neuropathic symptoms, such as burning in the feet.

A mixed small and large fiber dorsal root ganglionopathy in patients with Sjögren syndrome produces symptoms of kinesthesia and proprioception and may be associated with signs and symptoms of autonomic dysfunction (Chapter 386). Mononeuritis multiplex (involvement of two or more peripheral nerves) may develop in the setting of a systemic vasculitis and preferentially involves the longest peripheral nerves in the body. Cranial neuropathies most often target the trigeminal nerve ganglion, usually the maxillary and mandibular divisions while sparing the ophthalmic division.

Clinically significant disease of the central nervous system (CNS) is relatively uncommon in primary Sjögren syndrome, with a prevalence of 1 to 2%. CNS involvement can include optic neuropathy, focal central lesions, demyelinating lesions mimicking multiple sclerosis, cerebellar syndromes, movement disorders, neuromyelitis optica, encephalitis, aseptic meningitis, memory loss, impaired cognition, and transverse myelitis.

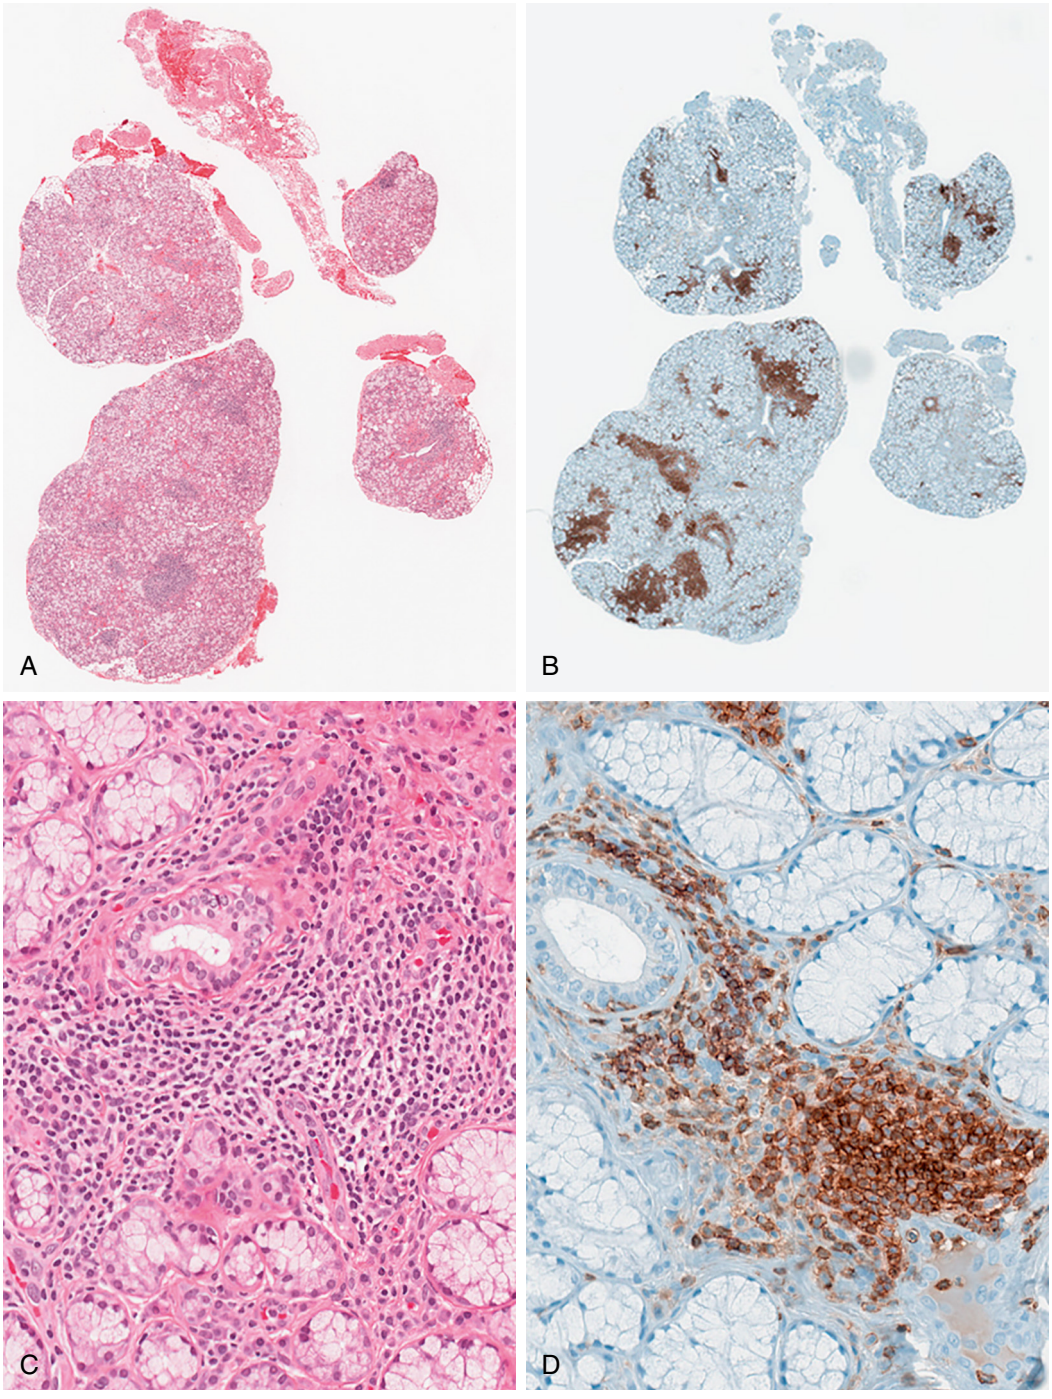
Rarely, patients with primary Sjögren syndrome develop an organ-threatening, systemic vasculitis, most commonly cryoglobulinemic vasculitis (Chapter 249).[11] Either type II or type III cryoglobulins may be detected in such cases. The dominant clinical features of cryoglobulinemic vasculitis are palpable purpura, peripheral neuropathy, and glomerulonephritis.

ABSTRACT

Sjögren syndrome, which is a systemic autoimmune disease, is characterized by glandular hypofunction and extraglandular manifestations. The hallmarks of the pathogenesis of Sjögren syndrome are genetic predisposition, evidence of immune dysregulation, and the production of autoantibodies. Histopathologic analysis of salivary gland tissue from patients with this disease reveals mostly infiltrating CD4+ T lymphocytes and B lymphocytes, with fewer numbers of CD8+ T lymphocytes, macrophages, and dendritic cells. Salivary gland epithelial cells display an activated phenotype and are presumed to play an important role in driving the chronic inflammatory response. The predominant glandular features are keratoconjunctivitis sicca, or dry eyes, and xerostomia, or dry mouth. It is termed *secondary* when these sicca manifestations are associated with another rheumatologic disease, such as rheumatoid arthritis or systemic lupus erythematosus, and termed *primary* otherwise. The extraglandular manifestations include polyarthralgia/polyarthritis, Raynaud syndrome, interstitial lung disease, peripheral neuropathy, interstitial nephritis, palpable purpura, hematologic abnormalities, and an increased risk for B-cell lymphoma. The classification of Sjögren syndrome is based on a scoring system, with points for meeting objective criteria for ocular dryness and salivary flow, a positive test for anti-SSA/Ro antibodies, and a positive labial salivary gland biopsy. The treatment of Sjögren syndrome is largely symptomatic and includes tear supplements, ophthalmic cyclosporine and other immunomodulators, and secretagogues such as pilocarpine and cevimeline. Severe extraglandular organ system involvement may require treatment with glucocorticoids and other immunosuppressive drugs. Although no disease-modifying drugs are approved for the treatment of Sjögren syndrome, several novel agents are under development for this indication.

KEYWORDS

Sjögren syndrome
anti-SSA/Ro antibodies
parotid gland enlargement
B-cell lymphoma
labial salivary gland biopsy



E-FIGURE 247-1. Histopathology of labial salivary glands in primary Sjögren syndrome. Hematoxylin and eosin staining (panels **A** and **C**) and anti-CD45 antibody staining (panels **B** and **D**) of labial salivary gland tissue. The low (4×) and high (20×) magnification views show the histopathologic findings of focal lymphocytic sialadenitis. Anti-CD45 antibodies stain only hematopoietic cells, including T lymphocytes, B lymphocytes, and other mononuclear cells. Multiple lymphocytic foci are evident among the different labial salivary gland lobules. The mononuclear cells can be seen to coalesce around ducts (panels **C** and **D**).

TABLE 247-1 2016 AMERICAN COLLEGE OF RHEUMATOLOGY/ EUROPEAN ALLIANCE FOR ASSOCIATIONS FOR RHEUMATOLOGY CLASSIFICATION FOR SJÖGREN SYNDROME

INCLUSION CRITERIA	
Any patient with at least 1 symptom of ocular or oral dryness or a suspicion of Sjögren syndrome	
ITEMS	**SCORE**
Histopathology showing focal lymphocytic sialadenitis with a focus score ≥1 per 4 mm^2[2*]	3
Positive test for anti-Ro/SSA antibodies	3
Ocular staining score ≥5[#,†]	1
Schirmer test ≤5 mm per 5 min in at least one eye	1
Unstimulated whole salivary flow rate <0.1 mL per minute[†]	1
RULES FOR CLASSIFICATION	
The classification of primary Sjögren syndrome is made in any individual who meets the inclusion criteria, does not have any exclusion criteria (prior diagnosis of any of the following conditions: history of head and neck radiation treatment, active hepatitis C infection, acquired immunodeficiency syndrome, sarcoidosis, amyloidosis, graft-versus-host disease, IgG4-related disease), and has a score ≥4 when the weights from the 5 criteria items are summed	

*The histopathologic examination should be performed by a pathologist with expertise in the diagnosis of focal lymphocytic sialadenitis and focus score count, using a specified protocol.
#Using lissamine green or fluorescein dye.
†Patients who are normally taking anticholinergic drugs should be evaluated for objective signs of salivary hypofunction and ocular dryness after a sufficient interval without these medications in order for these components to be a valid measure of oral and ocular dryness.
Based on Shiboski CH, Shiboski SC, Seror R, et al. 2016 American College of Rheumatology/ European League Against Rheumatism Classification Criteria for primary Sjogren's syndrome: a consensus and data-driven methodology involving three international patient cohorts. *Arthritis Rheumatol*. 2017;69:35-45.

Hematologic abnormalities are found in one-third of patients. Anemia is usually mild and has the features of anemia of chronic disease (Chapter 144). Thrombocytopenia, also usually mild, occurs in only about 2 to 3% of patients. Neutropenia, the most common hematologic abnormality, develops in 10 to 15% of patients, with neutrophil counts mostly ranging from 1000 to 2000/μL.

Lymphoma

The prevalence of non-Hodgkin lymphoma in primary Sjögren syndrome is 3 to 4%, but its risk increases about five-fold in patients who have neutropenia, low C4 levels, cryoglobulinemia, lymphadenopathy, or splenomegaly. The most common lymphoma associated with primary Sjögren syndrome is marginal zone B-cell lymphoma. Among the marginal zone B-cell lymphomas, the most common subtype is a mucosa-associated lymphoid tissue (MALT) lymphoma, which represents about 65% of all lymphomas that develop in patients with Sjögren syndrome. Other types with increased prevalence include lymphoplasmacytoid lymphoma, follicular cell lymphoma, and diffuse large B-cell lymphoma.

DIAGNOSIS

The diagnosis of primary Sjogren syndrome may be considered in any patient who has symptoms of dry eyes and dry mouth, or in a patient who has an extraglandular disorder typically associated with this disease. Consensus classification criteria (Table 247-1) have a sensitivity of 96% and a specificity of 95% for the diagnosis of primary Sjögren syndrome.

The diagnosis of dry eyes and dry mouth is aided by several objective testing methods. The aqueous component of the tear film may be quantified by a Schirmer test, which measures the distance tears elute on a strip of filter paper over 5 minutes. A distance of 5 mm or less is considered abnormal and consistent with the diagnosis of keratoconjunctivitis sicca. Vital dyes can be instilled into the eye to examine the conjunctival and corneal surface by slit lamp for any signs of damage (Chapter 391). Lissamine green dye stains the conjunctival and corneal surface and identifies degenerate cells, dead cells, and mucus (Fig. 247-1). Fluorescein dye also may be used to stain the corneal surface and to identify regions of cellular disruption.

Sialometry can measure salivary flow from individual glands (parotid, submandibular) or the mouth as a whole. In performing the test, the patient is asked to first clear their mouth of excessive saliva, then tilt their head forward and expectorate into a pre-weighed conical tube for 15 minutes. The collected samples are then weighed on an analytic balance to determine the volume (1 g = 1 mL). An unstimulated whole salivary flow rate ≤0.1 mL/minute is defined as impaired salivary flow. Ultrasonography, which can detect abnormalities in the salivary glands, has an 80% sensitivity and a 90% specificity for the diagnosis of primary Sjögren syndrome.[12]

Labial salivary gland biopsy, which is often considered the gold standard for diagnosing primary Sjögren syndrome, has a false-negative rate approaching 20%. Most patients do not require a labial salivary gland biopsy if the diagnosis is firmly established on the basis of clinical and serologic findings.

Laboratory Testing

Antinuclear antibodies (ANAs) are present in sera from most but not all patients with primary Sjögren syndrome. Two-thirds of patients test positive for anti-Ro/SSA antibodies and one-third for anti-La/SSB antibodies. About 50% of patients test positive for rheumatoid factor. A minority of patients, about 5%, test positive for anti-centromere antibodies, and their presence is associated with a higher rate of Raynaud syndrome and a higher risk of developing pulmonary hypertension. Other laboratory findings include hypergammaglobulinemia (IgG >1600 mg/dL), hypocomplementemia, and cryoglobulinemia. Serious organ system involvement is more likely in patients with serum anti-SSA/Ro antibodies, elevated serum levels of rheumatoid factor, hypergammaglobulinemia, cryoglobulinemia, and hypocomplementemia.

Extraglandular Disease

In patients with interstitial lung disease, pulmonary function studies show a restrictive pattern with reduced total lung capacity and a decrease in the diffusion capacity of lung carbon monoxide. In nonspecific interstitial pneumonitis, the chest computed tomographic (CT) findings consist of symmetrical, lower lobe, and peripherally predominant ground-glass opacities in a reticular nodular pattern, with relatively little evidence of fibrosis. Lymphocytic interstitial pneumonitis, a subset of nonspecific interstitial pneumonitis, produces a similar pattern of ground-glass opacities, as well as distinctive findings of thin-walled cysts, centrilobular nodules, interlobular septal thickening, and bronchovascular bundle thickening. In contrast, the chest CT findings of usual interstitial pneumonitis are characterized by heterogeneous, patchy, and irregularly distributed ground-glass opacities, lower lobe fibrosis, honeycombing, and traction bronchiectasis.

In the small fiber neuropathies of Sjögren syndrome, electrophysiologic studies are normal, and a skin biopsy demonstrating a reduced density of epidermal nerve fibers and sweat glands may be warranted to confirm the diagnosis. By comparison, electrophysiologic studies may show evidence of a large fiber, sensorimotor axonal peripheral neuropathy. With CNS involvement, brain magnetic resonance imaging (MRI) findings are usually nonspecific and consist of T2-weighted lesions resembling the microvascular changes associated with aging and cardiovascular disease. The cerebrospinal fluid may show abnormal findings of a lymphocytosis, an elevated IgG index, an increased protein level, and oligoclonal banding.

Differential Diagnosis

The differential diagnosis of primary Sjögren syndrome encompasses a wide range of disorders that also cause keratoconjunctivitis sicca, xerostomia, and parotid gland enlargement (Table 247-2), as well as diseases with similar extraglandular and laboratory features. The systemic disorders most frequently mimicking primary Sjögren syndrome are sarcoidosis (Chapter 83) and IgG4-related disease (Chapter 254), which may cause sicca symptoms and salivary gland enlargement, and also may affect multiple organ systems. In IgG4-related disease, the ANA is often negative, patients have high serum IgG4 levels, and their distinctive tissue histopathology is characterized by lymphoplasmacytic infiltrates, an abundance of IgG4-positive plasma cells, and storiform fibrosis. In addition, a Sjögren-like syndrome has been rarely described when patients with cancer receive checkpoint inhibitors targeting the programmed cell death (PD)-1/PD ligand-1 (PD-L1) pathway (e.g., pembrolizumab, nivolumab, and atezolizumab).

TABLE 247-2 DIFFERENTIAL DIAGNOSIS OF THE GLANDULAR MANIFESTATIONS OF SJÖGREN SYNDROME

DRY EYE (KERATOCONJUNCTIVITIS SICCA)
Aqueous tear deficiency
Sarcoidosis
Chronic hepatitis C infection
Chronic graft-versus-host disease
Sensory block (from corneal surgery, contact lens wear)
Motor block from cranial nerve VII damage
Medications*
Age-related degenerative process
Evaporative tear loss
Meibomian gland dysfunction
Cicatricial pemphigoid
Vitamin A deficiency
Poor lid congruity or low blink rate
DRY MOUTH (XEROSTOMIA DUE TO HYPOSALIVATION)
Sarcoidosis
Chronic hepatitis C infection
Chronic graft-versus-host disease
Amyloidosis
Hemochromatosis
Diabetes mellitus
Radiation therapy
Medications*
Anxiety
PAROTID GLAND ENLARGEMENT
IgG4-related disease
Sarcoidosis
Diffuse infiltrative lymphocytic syndrome (from uncontrolled HIV infection)
Benign tumors (e.g., pleomorphic adenoma, Warthin tumor, oncocytoma)
Malignant carcinoma (e.g., mucoepidermoid carcinoma, actinic cell carcinoma)
MALT lymphoma (also follicular cell and mantle cell lymphoma)
Primary T-cell lymphoma (e.g., HTLV-1 associated, anaplastic large cell, diffuse pleomorphic)
Sialadenosis (from diabetes mellitus, alcohol use disorder)
Calculous duct obstruction

*Includes anticholinergics, antihistamines, tricyclic antidepressants, antipsychotics, antispasmodics, isotretinoin, benzodiazepines, β-adrenergic blockers, α-adrenergic blockers, and diuretics.
HIV = human immunodeficiency virus; HTLV1 = human T-lymphotropic virus type 1; MALT = marginal zone lymphoma.

TREATMENT

Sicca Syndrome

No disease-modifying therapy is available for the treatment of primary Sjögren syndrome,[A1] so management is largely directed towards controlling symptoms unless the patient has serious organ system involvement.[13] The treatment of dry eyes relies on the liberal use of over-the-counter tear supplements, which provide a mucoprotective film, and lipid emollients, which stabilize the tear film. Gel lubricants are often used at bedtime.[14] Patients should avoid drafty environments, cigarette smoke, and other irritants. A humidifier may reduce evaporative tear loss.

Topical ophthalmic cyclosporine (0.05% or 0.09%) and lifitegrast, which is a lymphocyte function–associated antigen-1 (LFA-1) antagonist, are effective for reducing the symptoms of keratoconjunctivitis sicca, although results have been variable across clinical trials.[A2,A3] These treatments may cause stinging and burning, which limit their tolerability.

Tears may be conserved by blocking the inferior nasolacrimal ducts (and, if indicated, the superior punctae as well) with dissolvable collagen or silicone plugs. The ducts can be closed permanently by cauterization.

Meibomian gland dysfunction, which often occurs in conjunction with a deficiency of aqueous tears, may be managed with warm compresses, eyelid massage, lid scrubs, and dietary supplements containing omega-3 fatty acids. In more refractory cases, the application of a thermal pulsation device or treatment with oral doxycycline (50 to 100 mg once or twice daily for up to 1 month) may be helpful.

Symptoms of dry mouth (Chapter 393) may be improved by chewing sugarless gum or sucking on sugarless candy. Over-the-counter preparations of artificial saliva may provide short-term symptomatic relief. Two oral secretagogues, pilocarpine (5 mg four times daily) and cevimeline (30 mg three times daily), also can reduce the symptoms of dry mouth.[A4] Common side effects include sweating and flushing, increased urination, and nausea; these drugs are contraindicated in patients who have severe asthma, narrow angle glaucoma, and iritis. Patients are advised to visit their dentist regularly and utilize measures to prevent tooth decay. Oral candidiasis may be effectively treated with a 10- to 14-day treatment course of clotrimazole troches, five times daily, although fluconazole may be required in refractory cases (Chapter 310). Angular cheilitis may be managed by prescribing a 1- to 2-week course of 1% clotrimazole cream or with combined 1% clotrimazole/0.05% betamethasone cream applied twice daily to the corners of the mouth.

Dry lips are treated by applying lip balm or the oily content of vitamin E softgel capsules. Saline nasal spray or irrigation can moisturize dry nasal passages. Vaginal dryness with dyspareunia may respond favorably to application of local moisturizers, lubricants, or topical estrogen cream. Skin moisturizers are used for the treatment of dry skin.

Sudden onset of unilateral, painful parotid gland swelling (Chapter 393) is usually managed by warm compresses, gentle parotid gland massage, and a nonsteroidal anti-inflammatory drug (Table 26-4). These episodes, which are probably due to transient duct obstruction, tend to resolve within 2 to 5 days. If the swelling is refractory to this conservative approach, a short course of prednisone therapy under expert guidance often is rapidly effective in reducing the swelling, provided that the clinical presentation does not suggest an infectious etiology.

Extraglandular and Systemic Disease

Although hydroxychloroquine has often been recommended, the largest double-blind, placebo-controlled trial failed to show any significant benefit compared with placebo.[A5] The evidence supporting the use of methotrexate, sulfasalazine, or leflunomide for the treatment of Sjögren syndrome–associated inflammatory arthritis in this setting is indirect and based on their proven efficacy for the treatment of rheumatoid arthritis (Chapter 243).

Recurrent lower limb purpura may be treated with a short course of glucocorticoids (e.g., 0.5 mg/kg/day rapidly tapered to 5 mg/day over 2 weeks under expert supervision) to bring symptomatic relief. However, subsequent tapering

and withdrawal of glucocorticoids are generally met by a recurrence of the purpura. These repeated cycles of glucocorticoid therapy can often be avoided by treating recurrent purpura with support stockings, analgesics, antihistamines, and nonsteroidal anti-inflammatory drugs.

The sensory symptoms of a peripheral neuropathy (Chapter 388) are typically managed using medications such as gabapentin, pregabalin, and duloxetine and do not routinely call for glucocorticoid or other immunosuppressive therapy. The treatment of lymphoma depends on the site and stage of the disease (Chapter 171).

Organ-threatening extraglandular pulmonary[15] and renal disease usually warrants initial treatment with moderate to high doses of glucocorticoids (e.g., 0.5 mg/kg to 1 mg/kg/day of prednisone or its equivalent), often in combination with an adjunctive immunosuppressive agent, under expert supervision. Potential indications for such a treatment approach include active and progressive interstitial lung disease, interstitial nephritis, glomerulonephritis, serious nervous system involvement, or systemic vasculitis. Subcutaneous ianalumab showed some benefit in one study[A6] but remains experimental at this time. Rituximab, abatacept, tocilizumab, infliximab, and etanercept have been investigated for the treatment of Sjögren syndrome but have not proven effective in clinical trials. Other targeted therapies are in development.[16]

PROGNOSIS

Primary Sjögren syndrome is associated with significant morbidity due in large measure to dryness, fatigue, impaired sleep, psychological dysfunction, pain/articular involvement, sexual dysfunction, and reduced physical function.[17] Severe xerostomia may also lead to extensive loss of teeth and the need for dentures or implants. However, life expectancy is not reduced except in the subset of patients who have vasculitis, hypocomplementemia, cryoglobulinemia, or lymphoma.

248 INFLAMMATORY MYOPATHIES

STEVEN A. GREENBERG

DEFINITION

The inflammatory myopathies are a heterogeneous group of acquired disorders in which the immune system is thought to play a major pathogenic role.[1] Though some genetic disorders affecting muscle also have significant involvement of the immune system and are treated with immunosuppressive therapy as the standard of care (e.g., treatment of Duchenne muscular dystrophy with corticosteroids), these genetic disorders are not classified as inflammatory myopathies. The four major subtypes of inflammatory myopathy are dermatomyositis, polymyositis, immune-mediated necrotizing myopathy, and inclusion body myositis (also called sporadic inclusion body myositis). These disorders have distinct clinical and pathologic features and pathophysiologies (Table 248-1).[2,3]

EPIDEMIOLOGY

The prevalence of dermatomyositis has been estimated at 100 to 210 per million. The estimated prevalence of polymyositis is confounded by frequent misdiagnosis of inclusion body myositis and muscular dystrophies as polymyositis. Studies show a prevalence of 35 per million for polymyositis, approximately half of the 70 per million prevalence of inclusion body myositis. Inclusion body myositis is the most common acquired muscle disease after age 50 years.[4] The prevalence of immune-mediated necrotizing myopathy is unknown.

Dermatomyositis has biphasic peaks in incidence in childhood (ages 7 to 15 years) and in midlife (ages 30 to 50 years), whereas polymyositis peaks in incidence in midlife. Inclusion body myositis is rarely diagnosed before the age of 40 years and is most common after the age of 50 years. Dermatomyositis and polymyositis have female predominance, whereas inclusion body myositis has male predominance.

PATHOBIOLOGY

The pathophysiologies of various forms of inflammatory myopathy are poorly understood. These disorders do share in common injury to muscle by the immune system.[5] Much of the theory of pathophysiology of these disorders comes from microscopic examination of muscle biopsies and the distinct pathologies of these disorders (Fig. 248-1).

The muscle pathology of dermatomyositis involves loss of blood vessels and injury to myofibers at the edges of muscle fascicles (i.e., perifascicular atrophy; see Fig. 248-1). It is likely that a common factor injures both myofibers and capillaries. Skin pathology shows features analogous to that of muscle, with an interface dermatitis consisting of injury to the basal layer of keratinocytes.

Evidence points toward dermatomyositis as mediated by the type 1 interferon cytokine family, consisting mainly of interferon (IFN)-α and IFN-β. Studies of dermatomyositis skin and muscle samples show marked upregulation of type 1 IFN-inducible transcripts and proteins uniquely in dermatomyositis among muscle diseases and similarly to systemic lupus erythematosus (Chapter 245) among skin diseases. The presence of autoantibodies in some patients with dermatomyositis, such as antibodies to the type 1 IFN-inducible protein MDA5, is of uncertain significance but seems likely due to an immune reaction to proteins that are not normally expressed at high levels or exposed to the immune system.[6] The paraneoplastic associations of dermatomyositis suggest that an immune reaction against an underlying malignancy results in bystander injury to muscle and skin in such patients.[7]

Because polymyositis is a diverse group of disorders, the mechanisms involved are likely to be varied. Pathologically, nonspecific inflammation varies among the increasingly recognized distinct subtypes, such as the antisynthetase syndrome.

Immune-mediated necrotizing myopathy is also a poorly understood disorder. It can also be paraneoplastic, thereby suggesting cross-reactions by the immune system with the underlying malignancy and with muscle antigens. More commonly, immune-mediated necrotizing myopathy occurs in association with treatment with statin drugs (Chapter 190). The identification of autoantibodies against the target of statins, 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR), in the majority of patients who develop immune-mediated necrotizing myopathy in association with statin use suggests that the upregulation of HMGCR in muscle is directly toxic to muscle and triggers an immune reaction against it. Anti–signal recognition particle (SRP) autoantibodies have also been identified in some patients with immune-mediated necrotizing myopathy. Anti-SRP myopathy, anti-HMGCR myopathy, and autoantibody-negative myopathy have been considered to be three distinct subtypes of immune-mediated necrotizing myopathy.[8]

A genetic basis of inclusion body myositis has been suggested by its significant association with the class II MHC allele HLA-DRB1*03:01.[9] The pathogenesis of inclusion body myositis includes the destruction of myofibers by highly differentiated cytotoxic T cells.[10,11] Degeneration of myofibers and of myonuclei in particular, evident as formation of rimmed vacuoles, is likely a consequence of very chronic immune destruction of muscle (see Fig. 248-1A-C) and involvement of the immune system. Among all the inflammatory

and withdrawal of glucocorticoids are generally met by a recurrence of the purpura. These repeated cycles of glucocorticoid therapy can often be avoided by treating recurrent purpura with support stockings, analgesics, antihistamines, and nonsteroidal anti-inflammatory drugs.

The sensory symptoms of a peripheral neuropathy (Chapter 388) are typically managed using medications such as gabapentin, pregabalin, and duloxetine and do not routinely call for glucocorticoid or other immunosuppressive therapy. The treatment of lymphoma depends on the site and stage of the disease (Chapter 171).

Organ-threatening extraglandular pulmonary[15] and renal disease usually warrants initial treatment with moderate to high doses of glucocorticoids (e.g., 0.5 mg/kg to 1 mg/kg/day of prednisone or its equivalent), often in combination with an adjunctive immunosuppressive agent, under expert supervision. Potential indications for such a treatment approach include active and progressive interstitial lung disease, interstitial nephritis, glomerulonephritis, serious nervous system involvement, or systemic vasculitis. Subcutaneous ianalumab showed some benefit in one study[A6] but remains experimental at this time. Rituximab, abatacept, tocilizumab, infliximab, and etanercept have been investigated for the treatment of Sjögren syndrome but have not proven effective in clinical trials. Other targeted therapies are in development.[16]

PROGNOSIS

Primary Sjögren syndrome is associated with significant morbidity due in large measure to dryness, fatigue, impaired sleep, psychological dysfunction, pain/articular involvement, sexual dysfunction, and reduced physical function.[17] Severe xerostomia may also lead to extensive loss of teeth and the need for dentures or implants. However, life expectancy is not reduced except in the subset of patients who have vasculitis, hypocomplementemia, cryoglobulinemia, or lymphoma.

248 INFLAMMATORY MYOPATHIES

STEVEN A. GREENBERG

DEFINITION

The inflammatory myopathies are a heterogeneous group of acquired disorders in which the immune system is thought to play a major pathogenic role.[1] Though some genetic disorders affecting muscle also have significant involvement of the immune system and are treated with immunosuppressive therapy as the standard of care (e.g., treatment of Duchenne muscular dystrophy with corticosteroids), these genetic disorders are not classified as inflammatory myopathies. The four major subtypes of inflammatory myopathy are dermatomyositis, polymyositis, immune-mediated necrotizing myopathy, and inclusion body myositis (also called sporadic inclusion body myositis). These disorders have distinct clinical and pathologic features and pathophysiologies (Table 248-1).[2,3]

EPIDEMIOLOGY

The prevalence of dermatomyositis has been estimated at 100 to 210 per million. The estimated prevalence of polymyositis is confounded by frequent misdiagnosis of inclusion body myositis and muscular dystrophies as polymyositis. Studies show a prevalence of 35 per million for polymyositis, approximately half of the 70 per million prevalence of inclusion body myositis. Inclusion body myositis is the most common acquired muscle disease after age 50 years.[4] The prevalence of immune-mediated necrotizing myopathy is unknown.

Dermatomyositis has biphasic peaks in incidence in childhood (ages 7 to 15 years) and in midlife (ages 30 to 50 years), whereas polymyositis peaks in incidence in midlife. Inclusion body myositis is rarely diagnosed before the age of 40 years and is most common after the age of 50 years. Dermatomyositis and polymyositis have female predominance, whereas inclusion body myositis has male predominance.

PATHOBIOLOGY

The pathophysiologies of various forms of inflammatory myopathy are poorly understood. These disorders do share in common injury to muscle by the immune system.[5] Much of the theory of pathophysiology of these disorders comes from microscopic examination of muscle biopsies and the distinct pathologies of these disorders (Fig. 248-1).

The muscle pathology of dermatomyositis involves loss of blood vessels and injury to myofibers at the edges of muscle fascicles (i.e., perifascicular atrophy; see Fig. 248-1). It is likely that a common factor injures both myofibers and capillaries. Skin pathology shows features analogous to that of muscle, with an interface dermatitis consisting of injury to the basal layer of keratinocytes.

Evidence points toward dermatomyositis as mediated by the type 1 interferon cytokine family, consisting mainly of interferon (IFN)-α and IFN-β. Studies of dermatomyositis skin and muscle samples show marked upregulation of type 1 IFN-inducible transcripts and proteins uniquely in dermatomyositis among muscle diseases and similarly to systemic lupus erythematosus (Chapter 245) among skin diseases. The presence of autoantibodies in some patients with dermatomyositis, such as antibodies to the type 1 IFN-inducible protein MDA5, is of uncertain significance but seems likely due to an immune reaction to proteins that are not normally expressed at high levels or exposed to the immune system.[6] The paraneoplastic associations of dermatomyositis suggest that an immune reaction against an underlying malignancy results in bystander injury to muscle and skin in such patients.[7]

Because polymyositis is a diverse group of disorders, the mechanisms involved are likely to be varied. Pathologically, nonspecific inflammation varies among the increasingly recognized distinct subtypes, such as the antisynthetase syndrome.

Immune-mediated necrotizing myopathy is also a poorly understood disorder. It can also be paraneoplastic, thereby suggesting cross-reactions by the immune system with the underlying malignancy and with muscle antigens. More commonly, immune-mediated necrotizing myopathy occurs in association with treatment with statin drugs (Chapter 190). The identification of autoantibodies against the target of statins, 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR), in the majority of patients who develop immune-mediated necrotizing myopathy in association with statin use suggests that the upregulation of HMGCR in muscle is directly toxic to muscle and triggers an immune reaction against it. Anti–signal recognition particle (SRP) autoantibodies have also been identified in some patients with immune-mediated necrotizing myopathy. Anti-SRP myopathy, anti-HMGCR myopathy, and autoantibody-negative myopathy have been considered to be three distinct subtypes of immune-mediated necrotizing myopathy.[8]

A genetic basis of inclusion body myositis has been suggested by its significant association with the class II MHC allele HLA-DRB1*03:01.[9] The pathogenesis of inclusion body myositis includes the destruction of myofibers by highly differentiated cytotoxic T cells.[10,11] Degeneration of myofibers and of myonuclei in particular, evident as formation of rimmed vacuoles, is likely a consequence of very chronic immune destruction of muscle (see Fig. 248-1A-C) and involvement of the immune system. TABLE 248-1 CLASSIFICATION OF INFLAMMATORY MYOPATHIES

DISORDER	AGE RANGE	CLINICAL FEATURES	MUSCLE PATHOLOGY
Dermatomyositis	Juvenile and adult forms	Proximal weakness plus skin	Perimysial and perivascular inflammation, perifascicular atrophy
Polymyositis	Adult (rare in childhood)	Proximal weakness	Nonspecific inflammation
Immune-mediated necrotizing myopathy	Adult	Proximal weakness	Multifocal necrotic muscle fibers
Inclusion body myositis	Adult >40 years old	Prominent quadriceps and finger flexor weakness; treatment refractory	Endomysial inflammation with invasion of non-necrotic muscle fibers
Overlap syndromes	Adult	Myositis plus defined connective tissue disease	Nonspecific inflammation
Other (granulomatous myositis, eosinophilic myositis)	All ages	Proximal or distal weakness	Specific to type (e.g., granulomas present with granulomatous myositis)

myopathies, inclusion body myositis has the greatest evidence of a highly refined, antigen-driven, adaptive immune system response (Chapter 35). Pathology shows very chronic and often marked but variable inflammatory infiltrates of T cells, myeloid dendritic cells, and plasma cells in muscle. Studies of the T-cell receptors have strongly suggested that T-cell autoimmunity is driven by one or more specific antigens, though the identity of any of these antigens is unknown.

Studies of a B-cell pathway in inclusion body myositis have led to identification of circulating autoantibodies against a 43-kD muscle protein, identified as cytoplasmic 5′ nucleotidase 1 A (cN1A; NT5C1A). cN1A is a nucleotidase that is most abundant in skeletal muscle and is involved in the metabolism of nucleic acids. Serum anti-cN1A autoantibodies are present in 50 to 70% of patients with inclusion body myositis, depending on which assays and what cutoffs are used, and they are highly specific (>90 to 95%) for inclusion body myositis among muscle diseases.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

A diagnosis of inflammatory myopathy is considered when a patient presents with proximal or distal weakness without sensory symptoms or patients develop the characteristic skin lesions of dermatomyositis. Less frequently, asymptomatic elevated levels of creatine kinase lead to a diagnosis of inflammatory myopathy. Most patients with dermatomyositis, polymyositis, or immune-mediated necrotizing myopathy present with subacute proximal weakness of the arms and legs progressing over months, though these diseases may present acutely. Patients with inclusion body myositis present later in life, usually symptomatic from slowly progressive weakness of knee extensors and finger flexors. More specific diagnostic features of these disorders are considered individually (Table 248-2). Most patients undergo muscle biopsy (or skin biopsy in the case of suspected dermatomyositis) as part of the diagnostic evaluation.

Dermatomyositis

Patients with dermatomyositis typically present with characteristic skin lesions or muscle weakness.[12,13] Virtually pathognomonic skin features are a heliotrope rash, which is a violaceous periorbital macular erythema, sometimes with edema, and Gottron papules, which are violaceous papules over dorsal metacarpophalangeal and interphalangeal joints of the hands (Fig. 248-2). Periungual telangiectasias and thrombosed capillaries, poikiloderma over photoexposed areas such as the upper back ("shawl sign"), nonscarring alopecia, and subcutaneous calcification are other suggestive signs. Prominent pruritus is also a common feature of dermatomyositis. Muscle weakness in dermatomyositis is less specific and occurs in a pattern indistinguishable from many other muscle diseases.

Useful laboratory studies for the evaluation of suspected dermatomyositis include a serum creatine kinase level (though it can be normal or even below typical laboratory lower limits of normal in patients with highly active disease) and dermatomyositis-associated autoantibody studies (e.g., anti-Jo-1, anti-Mi2, and anti-MDA5). Occasional patients have an abnormal serum aldolase level but normal creatine kinase level. Skin biopsy showing a cell-poor interface dermatitis supports the diagnosis of dermatomyositis. Muscle biopsy showing perimysial and perivascular inflammation also supports a diagnosis of dermatomyositis, whereas the presence of perifascicular atrophy in a muscle biopsy is pathognomonic for dermatomyositis.[14]

Because dermatomyositis is associated with malignancy, appropriate laboratory and radiologic studies should be performed to search for underlying malignancy in all newly diagnosed patients.[15] As for unprovoked venous thrombosis, the evaluation should include a careful history and physical examination plus a complete blood count, urinalysis, serum chemistries, liver function tests, chest radiograph, stool for occult blood, and mammogram in woman and prostate-specific antigen in men. In addition, any abnormalities on these screening tests should be pursued aggressively. The most common dermatomyositis-associated malignancies tend to reflect the overall age and gender cancer rates within the individual patient's population (i.e., breast, lung, and colorectal cancer in Western countries; nasopharyngeal cancer in Asian populations). This observation supports the notion of dermatomyositis as a paraneoplastic process that can develop in virtually any kind of cancer.

The clinical features of muscle weakness in dermatomyositis are entirely nonspecific, with no particular pattern indicative of dermatomyositis compared with other muscle diseases.[16] In practice, certain dermatologic clinical findings (heliotrope rash, Gottron papules) or muscle biopsy findings (perifascicular atrophy) are considered nearly pathognomonic for dermatomyositis (Table 248-2).

Polymyositis

The diagnosis of polymyositis is often problematic, and many patients with genetically defined limb-girdle muscular dystrophies (Chapter 389) and inclusion body myositis can be misdiagnosed as polymyositis. The core criteria for the diagnosis of polymyositis are subacute proximal weakness, elevated serum creatine kinase level, and a muscle biopsy showing endomysial inflammation without features suggestive of another diagnosis such as inclusion body myositis (see Table 248-2). Patients with defined connective tissue disorders such as Sjögren syndrome (Chapter 247) or mixed connective tissue disease (Chapter 246) have "overlap syndromes," often also classified as polymyositis. Patients who actually have immune-mediated necrotizing myopathy are increasingly recognized. Patients with inclusion body myositis may be misdiagnosed as having polymyositis because of a lack of appreciation of the characteristic inclusion body myositis finger flexor weakness and because muscle biopsies show endomysial inflammation. The presence of autoantibodies such as anti-Jo-1 argue more for polymyositis than inclusion body myositis, though these antibodies may be seen in dermatomyositis as well. As with dermatomyositis, an evaluation for occult malignancy is indicated.

Immune-Mediated Necrotizing Myopathy

Immune-mediated necrotizing myopathy is increasingly distinguished from polymyositis.[17] Acute or subacute proximal weakness indistinguishable from that of polymyositis or dermatomyositis and an elevated creatine kinase level are nonspecific, but a muscle biopsy showing scattered necrotic or regenerating myofibers without inflammation other than macrophages invading these

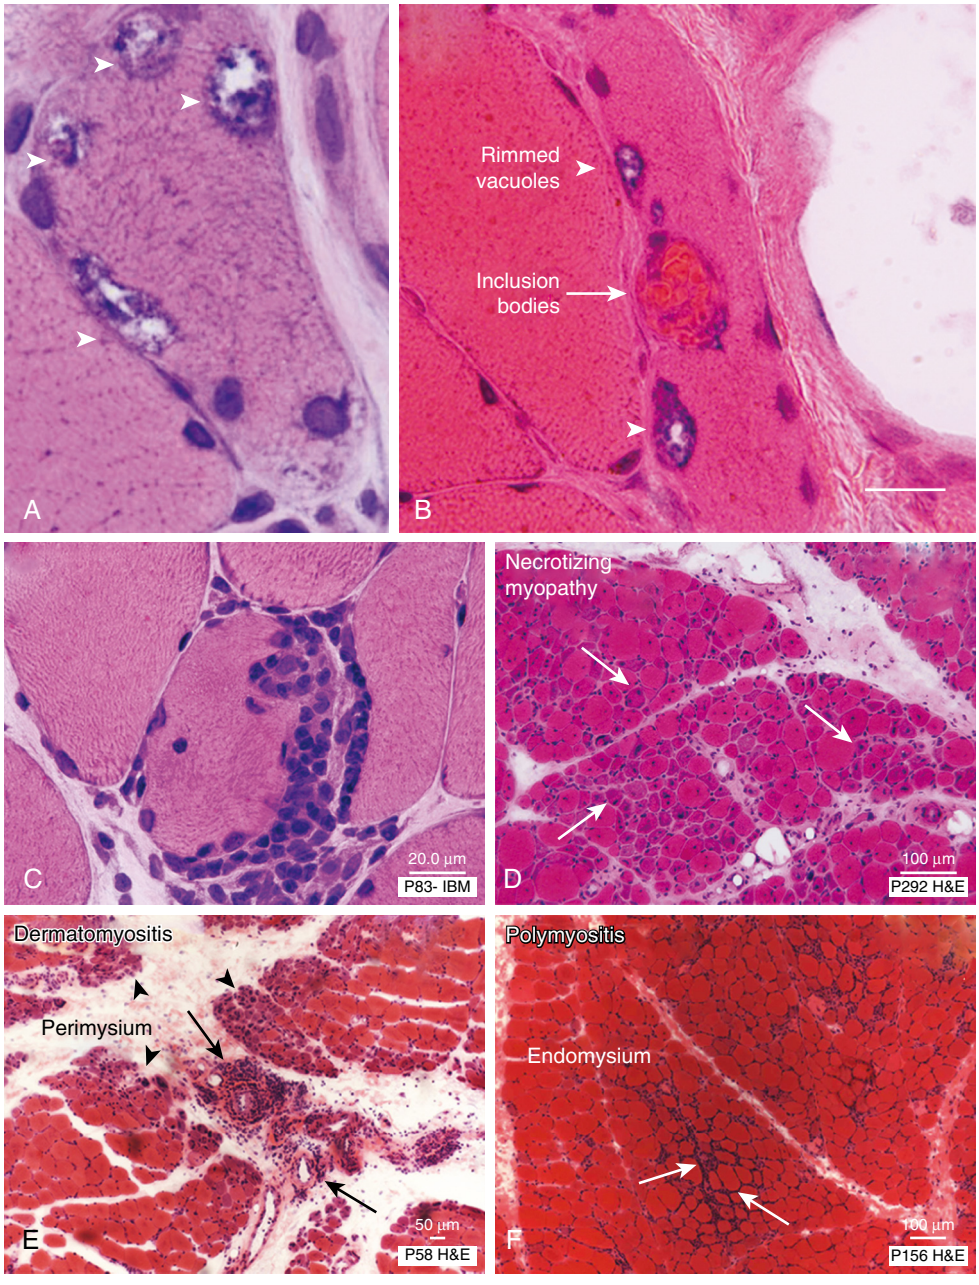

FIGURE 248-1. Pathologies of inflammatory myopathies. (With permission from the Inclusion Body Myositis Foundation, Inc.)

necrotic myofibers is typical of immune-mediated necrotizing myopathy. The presence of anti-HMGCR (3-hydroxy-3-methylglutaryl-coenzyme A reductase) or anti-SRP (signal recognition particle) antibodies suggest immune-mediated necrotizing myopathy.[18] Immune-mediated necrotizing myopathy, particularly when associated with anti-SRP antibodies, may be paraneoplastic, and laboratory and radiologic evaluation for malignancy should be considered as for dermatomyositis.

Inclusion Body Myositis

Inclusion body myositis has a clinical presentation distinct from other inflammatory myopathies.[19] Weakness is always slowly progressive rather than the acute or subacute weakness more typically seen in other forms of inflammatory myopathies (see Table 248-2). Inclusion body myositis is misdiagnosed in approximately 50% of patients. Symptoms of inclusion body myositis rarely are present before age 40 years and most commonly occur after age 50 years. The distribution of weakness is usually in finger flexors or quadriceps, as compared with the proximal arm (shoulder abduction) or proximal leg (hip flexion) weakness that is more typical of polymyositis or dermatomyositis.

Inclusion body myositis is a highly atrophying muscle disease,[20] and loss of bulk in medial and lateral anterior thighs and ventral forearms is characteristic. Patients present with difficulty walking, buckling of knees, or weakness of grip. The diagnosis of inclusion body myositis can be highly suspected when patients of appropriate age have findings of quadriceps atrophy and weakness of finger flexors, especially of the flexor digitorum profundus that are responsible for flexion of distal fingertips. Examination of the strength in these distal fingertips, which must be done one finger at a time, is often the single most helpful approach to the diagnosis of inclusion body myositis.

The serum creatine kinase is either normal or modestly elevated (typically less than five times the upper limit of normal). A serum autoantibody, anti-cN1A (also called anti-NT5C1A),[21] is highly specific for inclusion body myositis among muscle diseases. Most patients undergo muscle biopsy, with the characteristic features being the presence of rimmed vacuoles on hematoxylin and eosin and Gomori trichrome staining, as well as endomysial inflammation or invasion of non-necrotic muscle fibers. Immunohistochemical stains detecting p62 or TDP-43 are of additional highly specific diagnostic value.

TABLE 248-2 CLINICAL DIAGNOSTIC CRITERIA FOR INFLAMMATORY MYOPATHIES

DISORDER	DIAGNOSIS
Dermatomyositis	1. Diagnostic skin involvement (heliotrope rash, Gottron papules) *OR* diagnostic muscle biopsy finding of perifascicular atrophy *OR* 2. All of the following: • Suggestive skin involvement • Subacute or chronic proximal or distal weakness • Muscle biopsy showing perimysial or perivascular inflammation without features suggesting another disorder (e.g., endomysial inflammation, rimmed vacuoles) *OR* skin biopsy showing interface dermatitis along with clinical exclusion of systemic lupus erythematosus
Polymyositis	All of the following: 1. Subacute or chronic proximal weakness 2. Elevated serum creatine kinase (CK) 3. Muscle biopsy showing invasion of endomysial inflammation 4. Response to immunotherapy *OR* appropriate consideration and exclusion of limb-girdle muscular dystrophies and inclusion body myositis
Immune-mediated necrotizing myopathy	Both of the following: 1. Subacute or chronic proximal weakness 2. Muscle biopsy showing necrotizing myopathy, with scattered necrotic or regenerating myofibers and a lack of inflammation other than macrophage invasion of necrotic muscle fiber
Inclusion body myositis	All of the following: 1. Adult >40 years old 2. Finger flexion or quadriceps weakness 3. Muscle biopsy showing endomysial inflammation *OR* the presence of serum anti-cN1A autoantibodies 4. Muscle biopsy showing rimmed vacuoles *OR* invasion of non-necrotic muscle fibers *OR* the presence of serum anti-cN1A autoantibodies

cNIA = cytoplasmic 5′ nucleotidase 1A.

TREATMENT

Generally, most patients with dermatomyositis, polymyositis, and immune-mediated necrotizing myopathy respond to immunomodulatory therapies, whereas patients with inclusion body myositis are almost universally refractory (Fig. 248-3).[22]

Treatment of Dermatomyositis and Polymyositis

Most patients with muscle involvement from dermatomyositis and polymyositis are treated with and respond to corticosteroids.[23,24] Dosing is typically prednisone at 1 mg/kg/day orally until significant improvement occurs (typically 1 to 3 months), followed by gradual taper of 10 mg/day/month. Apremilast also may be useful for recalcitrant cutaneous dermatomyositis.[25] Second-line agents under expert guidance include methotrexate, azathioprine, cyclosporine, and intravenous immunoglobulin.[A1] Second-line agents are used for two reasons: they may have a better side-effect profile than chronic higher doses of corticosteroids, and they may be necessary for patients whose responses are insufficient to corticosteroids alone. An important decision is whether to start second-line agents concurrently with initial corticosteroid treatment or wait and see how low a dose of corticosteroids offers satisfactory control and then add agents only if the corticosteroid dose cannot be lowered sufficiently. Thus, in the former approach, prednisone 60 mg/day and methotrexate 7.5 mg orally weekly might be started concurrently and the methotrexate dose increased to 15 to 20 mg orally weekly. Once improvement is substantial, the dose of prednisone may be tapered over 3 to 6 months. Stability on methotrexate alone would then be followed by gradual reduction in its dose. For patients with severe initial presentations, the combination of corticosteroids and periodic intravenous immunoglobulin (1 g/kg every 2 weeks) may offer a better chance for more rapid improvement.

Treatment of Inclusion Body Myositis

No therapies have demonstrated efficacy for inclusion body myositis, with negative results for prednisone, intravenous immunoglobulin, methotrexate, antithymocyte globulin, etanercept, interferon-β, and alemtuzumab. Current management of patients with inclusion body myositis is supportive, including avoidance of falls and the use of ankle supports and gait assistive devices. Tendon transfer has been used to improve hand function.

PROGNOSIS

Most patients with adult dermatomyositis, polymyositis, and statin-associated immune-mediated necrotizing myopathy have a good prognosis with chronic immunomodulatory therapy. However, the annual hazard ratio for death is about five-fold higher than in the general population.[26] Patients with anti-SRP–associated immune-mediated necrotizing myopathy may have severe and difficult-to-treat disease. Patients with inclusion body myositis generally have a slowly progressive course, with one series showing a mean time to loss of ambulation of 12 years and a mean of survival of 14 years.[27]

249 THE SYSTEMIC VASCULITIDES

JOHN H. STONE

DEFINITION

The vasculitides are a heterogeneous group of disorders linked by the common finding of destructive inflammation within blood vessel walls. The most current nomenclature scheme identifies at least 27 different forms of primary vasculitis (Table 249-1).

CLASSIFICATION

Classification by Vessel Size

The etiology of most forms of vasculitis remains unknown, and major gaps exist in our understanding of the pathophysiologic processes. The most valid basis for classification of the vasculitides is the size of the predominant blood vessels involved. The vasculitides are categorized initially by whether the vessels affected are primarily large, medium, or small (see Table 249-1). Large vessels are considered the aorta, its primary branches, and any vessel that is not located within an organ such as a muscle, kidney, nerve, or the skin. Medium-sized vessels, in contrast, consist of the main visceral arteries and their branches. Thus, the renal artery is considered a large vessel, but its intrarenal branches—the interlobar and arcuate arteries—are medium-sized vessels. Finally, small vessels include smaller intraparenchymal arteries as well as arterioles, capillaries, and venules.

Medium-vessel vasculitis and even large-vessel vasculitis can also affect small arteries. However, large-vessel vasculitis affects large arteries more often than medium- or small-vessel vasculitis, medium-vessel vasculitis affects predominantly medium arteries, and small-vessel vasculitis affects predominantly arterioles, capillaries, and venules.

Additional Considerations in Classification

Considerations other than the size of blood vessels that are relevant to the classification of vasculitis (see Table 249-2) include age, sex, and ethnic background of the patient; organ tropism; presence or absence of granulomatous inflammation; participation of immune complexes in the pathophysiologic process; and detection of characteristic autoantibodies, such as antineutrophil cytoplasmic antibodies (ANCAs), in the patient's serum.

The organ tropisms of these disorders are illustrated by the following examples. Whereas immunoglobulin (Ig)A vasculitis (also known as Henoch-Schönlein purpura) typically affects the skin, joints, kidneys, and the gastrointestinal tract, granulomatosis with polyangiitis classically involves the upper airways, lungs, and kidneys. In contrast to both IgA vasculitis and granulomatosis with polyangiitis, Cogan syndrome involves the eyes, the audiovestibular apparatus of the inner ear, and (in 10 to 15% of cases) the large arteries.

The presence or absence of granulomatous inflammation is a crucial element in the diagnosis and classification of vasculitis. The small number of vasculitides

249 THE SYSTEMIC VASCULITIDES

JOHN H. STONE

DEFINITION

The vasculitides are a heterogeneous group of disorders linked by the common finding of destructive inflammation within blood vessel walls. The most current nomenclature scheme identifies at least 27 different forms of primary vasculitis (Table 249-1).

CLASSIFICATION

Classification by Vessel Size

The etiology of most forms of vasculitis remains unknown, and major gaps exist in our understanding of the pathophysiologic processes. The most valid basis for classification of the vasculitides is the size of the predominant blood vessels involved. The vasculitides are categorized initially by whether the vessels affected are primarily large, medium, or small (see Table 249-1). Large vessels are considered the aorta, its primary branches, and any vessel that is not located within an organ such as a muscle, kidney, nerve, or the skin. Medium-sized vessels, in contrast, consist of the main visceral arteries and their branches. Thus, the renal artery is considered a large vessel, but its intrarenal branches—the interlobar and arcuate arteries—are medium-sized vessels. Finally, small vessels include smaller intraparenchymal arteries as well as arterioles, capillaries, and venules.

Medium-vessel vasculitis and even large-vessel vasculitis can also affect small arteries. However, large-vessel vasculitis affects large arteries more often than medium- or small-vessel vasculitis, medium-vessel vasculitis affects predominantly medium arteries, and small-vessel vasculitis affects predominantly arterioles, capillaries, and venules.

Additional Considerations in Classification

Considerations other than the size of blood vessels that are relevant to the classification of vasculitis (see Table 249-2) include age, sex, and ethnic background of the patient; organ tropism; presence or absence of granulomatous inflammation; participation of immune complexes in the pathophysiologic process; and detection of characteristic autoantibodies, such as antineutrophil cytoplasmic antibodies (ANCAs), in the patient's serum.

The organ tropisms of these disorders are illustrated by the following examples. Whereas immunoglobulin (Ig)A vasculitis (also known as Henoch-Schönlein purpura) typically affects the skin, joints, kidneys, and the gastrointestinal tract, granulomatosis with polyangiitis classically involves the upper airways, lungs, and kidneys. In contrast to both IgA vasculitis and granulomatosis with polyangiitis, Cogan syndrome involves the eyes, the audiovestibular apparatus of the inner ear, and (in 10 to 15% of cases) the large arteries.

The presence or absence of granulomatous inflammation is a crucial element in the diagnosis and classification of vasculitis. The small number of vasculitides

ABSTRACT

The vasculitides are a heterogeneous group of disorders linked by the common finding of destructive inflammation within blood vessel walls. The current Chapel Hill Consensus on nomenclature identifies at least 27 different forms of primary vasculitis. The vasculitides are classified first according to the size of the blood vessel involved—small, medium, or large—but also according to whether their pathology is characterized by granulomatous inflammation, eosinophilic infiltrates, intense immune complex deposition, and other features. Patients with some forms of vasculitis (e.g., the group associated with antineutrophil cytoplasmic antibodies) typically have disease-specific autoantibodies in their blood.

KEYWORDS

systemic vasculitis
antineutrophil cytoplasmic antibody (ANCA) positive vasculitis
giant cell arteritis
Takayasu vasculitis (arteritis)
polyarteritis nodosa
Kawasaki disease
granulomatosis with polyangiitis (formerly Wegener)
eosinophilic granulomatosis with polyangiitis (EGPA formerly Churg-Strauss)
Behçet syndrome
IgA vasculitis

TABLE 249-1 NAMES FOR VASCULITIDES ADOPTED BY THE 2012 INTERNATIONAL CHAPEL HILL CONSENSUS CONFERENCE ON THE NOMENCLATURE OF VASCULITIDES

LARGE-VESSEL VASCULITIS
Takayasu arteritis
Giant cell arteritis
MEDIUM-VESSEL VASCULITIS
Polyarteritis nodosa
Kawasaki disease
Buerger disease*
SMALL-VESSEL VASCULITIS
Antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis
Microscopic polyangiitis
Granulomatosis with polyangiitis (formerly Wegener granulomatosis)
Eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome)
Immune complex small-vessel vasculitis
Antiglomerular basement membrane disease
Cryoglobulinemic vasculitis
Immunoglobulin (Ig)A vasculitis (Henoch-Schönlein purpura)
Hypocomplementemic urticarial vasculitis
VARIABLE-VESSEL VASCULITIS
Behçet syndrome
Cogan syndrome
SINGLE-ORGAN VASCULITIS
Cutaneous leukocytoclastic angiitis
Cutaneous arteritis
Primary central nervous system vasculitis
Isolated aortitis
VASCULITIS ASSOCIATED WITH SYSTEMIC DISEASE
Lupus vasculitis
Rheumatoid vasculitis
Sarcoid vasculitis
IgG4-related disease
Others
VASCULITIS ASSOCIATED WITH PROBABLE ETIOLOGY
Hepatitis C virus–associated cryoglobulinemic vasculitis
Hepatitis B virus–associated vasculitis
Syphilis-associated aortitis
Drug-associated immune complex vasculitis
Drug-associated ANCA-associated vasculitis
Cancer-associated vasculitis
Others

*Buerger disease (thromboangiitis obliterans) is not always considered to be a primary form of vasculitis and was not included in this consensus statement on nomenclature.

TABLE 249-2 CONSIDERATIONS IN THE CLASSIFICATION OF SYSTEMIC VASCULITIS

Size of predominant blood vessels affected
Epidemiologic features:
Age
Sex
Ethnic background
Pattern of organ involvement
Pathologic features:
Granulomatous inflammation
Immune complex deposition vs. "pauci-immune" histopathology
Presence of ANCA in serum

ANCA = antineutrophil cytoplasmic antibody.

that demonstrate granulomatous inflammation includes granulomatosis with polyangiitis, giant cell arteritis, Takayasu arteritis, and eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome).

Immune complexes are essential to the pathophysiologic mechanism of some forms of small- and medium-vessel vasculitis. Complexes of IgA1, for example, are found in IgA vasculitis. Immune complexes consisting of IgG, IgM, complement components, and the hepatitis C virion characterize most cases of mixed cryoglobulinemia. In contrast, "pauci-immune" types of small- and medium-vessel vasculitis, such as granulomatosis with polyangiitis and microscopic polyangiitis, have comparatively little evidence of immune complex deposition within diseased tissues. Many, but not all, patients with pauci-immune forms of vasculitis are positive for antineutrophil cytoplasmic antibodies (ANCA).

EPIDEMIOLOGY

The epidemiologic features of individual forms of systemic vasculitis vary tremendously by geography (Table 249-3)[1] as a reflection of genetic influences, variations in environmental exposures, and other unknown risk factors. For example, whereas Behçet syndrome is rare in North Americans, affecting only 1 person in approximately 300,000, this condition is several hundred times more common among inhabitants of countries bordering the ancient Silk Route. Similarly, although Takayasu arteritis (Chapter 63) is rare in the United States—on the order of 3 new cases per million people per year—this disease is reportedly the most common cause of renal artery stenosis in India, where the incidence may be as high as 200 to 300 per million per year.

Age is an important consideration in the epidemiology of vasculitis. Eighty percent of patients with Kawasaki disease are younger than age 5 years. In contrast, giant cell arteritis virtually never occurs in patients younger than age 50 years, and the mean age of patients with this disease is 72 years. Age may also have an impact on disease severity and outcome. In IgA vasculitis, the overwhelming majority of cases in children (who represent 90% of all cases) have self-limited courses, resolving within several weeks. In adults, however, IgA vasculitis has a higher likelihood of chronicity and a poor renal outcome.

The distribution of sex varies across many forms of vasculitis. The vasculitis associated with IgG4-related disease (e.g., aortitis, coronary arteritis, and even small-vessel vasculitis) is more likely to occur in males. Buerger disease (Chapter 66), which is often considered a form of vasculitis albeit not included in the Chapel Hill consensus nomenclature, has a striking male predominance that is probably explained by the higher prevalence of smoking among males in most societies. In contrast, Takayasu arteritis has an overwhelming tendency to occur in females (a 9 : 1 female-to-male ratio). The pauci-immune forms of vasculitis, such as granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis, and microscopic polyangiitis, occur in males and females with approximately equal frequencies, but the phenotypic expression of these conditions may be affected by both age and sex. As an example, granulomatosis with polyangiitis limited to the subglottic region is more likely to occur in female patients.

The strongest link between any single gene and vasculitis is the association of *HLA-B51* with Behçet syndrome. In Behçet syndrome, 80% of Asian patients have the *HLA-B51* gene. The prevalence of *HLA-B51* is significantly higher among patients with Behçet syndrome in Japan than among nondisease control subjects (55% versus <15%). Among the sporadic cases of Behçet syndrome involving Whites in the United States, however, *HLA-B51* occurs in less than 15% of cases.

With the exception of Buerger disease and smoking, no definitive associations have been confirmed between disease and environmental or occupational exposures. Associations have been reported but not confirmed between exposures to silica and some types of pauci-immune vasculitis. Studies of potential associations between exposures of any type and vasculitis, however, are frequently complicated by difficulties in obtaining reliable measurements of the levels of the relevant exposure, the likelihood of recall bias among patients who are diagnosed with vasculitis, and the choice of appropriate control groups.

PATHOBIOLOGY

Different forms of vasculitis have different pathologic characteristics (Table 249-4). The type of inflammatory cell infiltrate in vasculitis is independent of the size of blood vessels involved. Mixed cell infiltrates in vasculitis are the rule rather than the exception, and histopathologic patterns of vasculitis may include leukocytoclasis (degranulation and destruction of neutrophils within blood vessel walls), granulomatous findings (with or without giant cells), lymphoplasmacytic infiltrates, varying degrees of eosinophilic infiltration, necrosis, and combinations of all these findings.

Pathophysiology

Some pathophysiologic mechanisms are common to many different forms of vasculitis, regardless of the size of the predominant blood vessels involved.

TABLE 249-3 EPIDEMIOLOGY OF SELECTED VASCULITIDES

DISEASE	UNITED STATES	ELSEWHERE	AGE, SEX, AND ETHNIC PREDISPOSITIONS
Giant cell arteritis	Incidence: 240/million (Olmsted County, MN)	220-270/million (Scandinavian countries)	Age >50 yr, mean age 72 yr; females 3 : 1; Northern European ancestry
Takayasu arteritis	Incidence: 3/million	200-300/million (India)	Age <40 yr; females 9 : 1; Asian
Behçet syndrome	Prevalence: 3/million	3000/million (Turkey)	Silk Route countries
Polyarteritis nodosa	Incidence: 7/million	7/million (Spain)	Slight male predominance
Kawasaki disease	Incidence: 100/million*	900/million (Japan)	Children of Asian ancestry
Granulomatosis with polyangiitis	Incidence: 4/million	8.5/million (United Kingdom)	Whites >> Blacks

*Among children younger than 5 years.

TABLE 249-4 PATHOLOGIC CHARACTERISTICS OF SELECTED FORMS OF VASCULITIS

	TAKAYASU ARTERITIS	POLYARTERITIS NODOSA	GRANULOMATOSIS WITH POLYANGIITIS (WEGENER GRANULOMATOSIS)	EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS*	HENOCH-SCHÖNLEIN PURPURA	CUTANEOUS LEUKOCYTOCLASTIC ANGIITIS
Vessels involved	Elastic (large) or muscle (medium-sized) arteries	Medium-sized and small muscle arteries	Small arteries and veins; sometimes medium-sized vessels	Small arteries and veins; sometimes medium-sized vessels	Capillaries, venules, and arterioles	Capillaries, venules, and arterioles
Organ involvement	Aorta, aortic arch and major branches, and pulmonary arteries	Skin, peripheral nerves, gastrointestinal tract, and other viscera	Upper respiratory tract, lungs, kidneys, skin, eyes	Upper respiratory tract, lungs, heart, peripheral nerves	Skin, joints, gastrointestinal tract, kidneys	Skin, joints
Type of vasculitis and inflammatory cells	Granulomatous with some giant cells; fibrosis in chronic stages	Necrotizing, with mixed cellular infiltrate	Necrotizing or granulomatous (or both); mixed cellular infiltrate plus occasional eosinophils	Necrotizing or granulomatous (or both); prominent eosinophils and other mixed infiltrate	Leukocytoclastic, with some lymphocytes and variable eosinophils; IgA deposits in affected tissues	Leukocytoclastic, with occasional eosinophils

*Formerly named Churg-Strauss syndrome.
Ig = immunoglobulin.

Immune complex deposition, for example, is present in several types of vasculitis that involve both medium-sized and small blood vessels.

Large-Vessel Vasculitides

The pathologic process in large-vessel vasculitis appears to begin in the adventitia. In both Takayasu arteritis (Chapter 63) and giant cell arteritis (Chapter 250), abundant numbers of activated T lymphocytes are found within inflamed arterial walls, centering on the adventitia. In Takayasu arteritis, most of these T cells appear to be of the $CD8^+$ subtype. Current evidence suggests that the cytotoxic functions of these cells, mediated by perforin and granzyme B, contribute to smooth muscle cell damage in this disease. $CD4^+$ T-cell responses in Takayasu arteritis have not been well defined.

In giant cell arteritis (Chapter 250), evidence suggests an antigen-driven disease, with the site of immunologic events being the adventitia. $CD4^+$ T cells that secrete interferon (IFN)-γ appear to be recruited to the adventitia by a specific antigen(s), the identity of which remains unknown. Both the T cells that orchestrate the transmural inflammation and the inciting antigens are theorized to reach the adventitia through the vasa vasorum. Subsequently, T-cell signals from the adventitia stimulate macrophages and multinucleated giant cells to elaborate an array of downstream mediators, including metalloproteinases and platelet-derived growth factor. Interleukin (IL)-6, known to be a crucial cytokine in giant cell arteritis and probably Takayasu arteritis, is also produced by macrophages residing in the blood vessel wall. The results of this inflammatory cascade are granulomatous inflammation, destruction of the internal elastic lamina, arterial wall hyperplasia, smooth muscle cell proliferation, intimal thickening, vascular occlusion, and, in some cases, weakening of the vessel wall with subsequent dilation and aneurysm formation. Matrix metalloproteinases appear to play important roles in destruction of the internal elastic lamina, damage to other vascular tissues, and weakening of the arterial wall.

Medium- and Small-Vessel Vasculitides

Several different pathophysiologic mechanisms are operative among the medium- and small-vessel vasculitides.

Immune Complex–Mediated Vascular Injury

Immune complex–mediated tissue injury does not produce a single clinical syndrome but rather applies to many forms of vasculitis and overlaps with injuries caused by other immune mechanisms. Numerous variables influence immune complex–mediated injury, including the physical properties of the immune complexes (e.g., their size), the ability of the immune complexes to activate complement, the antigen-to-antibody ratio, and the hemodynamic features of specific vascular beds. Immune complexes participate in the pathophysiologic process of some forms of both medium- and small-vessel vasculitis, including polyarteritis nodosa, cryoglobulinemia, IgAV, cutaneous leukocytoclastic angiitis, and rheumatoid vasculitis.

Role of Antineutrophil Cytoplasmic Antibodies

Antineutrophil cytoplasmic antibodies (ANCAs) are directed against antigens that reside within the primary granules of neutrophils and monocytes. Two types of ANCA are relevant to vasculitis: (1) those directed against proteinase 3 (PR3), known as PR3-ANCA, and (2) those directed against myeloperoxidase (MPO), termed MPO-ANCA. ANCAs interact with cytokines, neutrophils, monocytes, and other elements of the immune system to amplify ongoing inflammation in certain forms of vasculitis. A striking and still unexplained feature of ANCA-associated vasculitis is that patients with primary forms of these conditions virtually never have antibodies to both PR3 and MPO.

Despite the specificity of these antibodies, however, evidence for a primary role of ANCA in the etiology of human disease is still tenuous.

In granulomatosis with polyangiitis, abnormal cytokine regulation interacts with the production of antineutrophil cytoplasmic antibodies to fuel the inflammatory response. T_H1 cytokines such as interferon (IFN)-γ, interleukin (IL)-12, and tumor necrosis factor (TNF) appear to play important roles. Under the direction of IL-12, $CD4^+$ T cells from patients with granulomatosis with polyangiitis produce elevated levels of TNF, and peripheral blood mononuclear cells secrete increased amounts of IFN-γ. Serum levels of soluble receptors for TNF are elevated in patients with active granulomatosis with polyangiitis and normalize with the induction of remission. In vitro priming of activated neutrophils with TNF markedly enhances the ability of ANCA to stimulate neutrophil degranulation. Through processes, which are promoted by a variety of cytokines, ANCA binding leads to neutrophil activation and degranulation, with the release of cytotoxic substances and activation of the alternative complement pathway.

The effectiveness of B-cell depletion for the treatment of antibody-associated vasculitis probably relates to the removal of several B-cell functions beyond their evolution into plasma cells and the production of ANCA. Such functions include the production of cytokines, the presentation of antigen, and B cell–T cell crosstalk. B-cell depletion is emerging rapidly as the treatment of choice for some forms of severe vasculitis.

Superantigen Model

The degree of immune activation in Kawasaki disease and the acute but generally self-limited nature of this illness imply a potential role for superantigens. Superantigens are proteins that are produced by microbial pathogens (e.g., *Staphylococcus aureus* or *Streptococcus* species) and that are capable of stimulating large populations of T cells in a manner unrestricted by the class II major histocompatibility complex (MHC). Superantigens bind directly to conserved amino acid residues outside the antigen-binding groove on class II MHC molecules, thereby selectively stimulating T cells that express particular β-chain variable gene segments. Through the binding of this MHC-superantigen complex to its cognate T-cell receptors, as many as 20% of circulating lymphocytes may become activated, thereby leading to a potentially enormous outpouring of cytokines. With regard to the etiology of Kawasaki disease, substantial attention has focused on toxic shock syndrome toxin 1, an exotoxin produced by *S. aureus*. Superantigens have also been postulated to play roles in the susceptibility to disease flares in granulomatosis with polyangiitis. Compelling laboratory and naturally occurring animal models of disease, combined with the known associations of hepatitis B virus and hepatitis C virus with vasculitis in humans, suggest that additional links between infection and systemic vasculitis may be established in the future.

Anti–Endothelial Cell Antibodies

Anti–endothelial cell antibodies can induce endothelial cell injury and lysis through either complement-mediated cytotoxicity or antibody-dependent cellular cytotoxicity. The ability of these antibodies to damage endothelial cells is an appealing argument for their potential role in forms of vasculitis in which the endothelium is the focus of the inflammation (as opposed to the more external vessel wall layers).

DIAGNOSIS

Vasculitis is often considered in patients who have multisystem diseases or fever of unknown origin (Chapter 259). The major categories of disease that can mimic vasculitis are also multisystem diseases (Table 249-5).

Certain features of a patient's case should raise the diagnostic suspicion for vasculitis. First, most cases of vasculitis do not begin suddenly but rather unfold subacutely during weeks or months. Second, pain is usually a prominent feature of vasculitis as a result of arthritis or arthralgias, myalgias, headaches, neuropathy, testicular infarction, digital ischemia, sinusitis, otalgia, back pain (caused by aortic inflammation), postprandial abdominal pain (caused by mesenteric vasculitis), or other disease manifestations. Third, signs of inflammation such as fever, rash, weight loss, and elevated acute phase reactants are highly characteristic. Finally, multiorgan system involvement is the rule in vasculitis.

The diagnosis of vasculitis should be established through biopsy of an involved organ whenever possible. Diagnoses based on angiography alone have many potential pitfalls, and angiographic findings that are called "consistent with vasculitis" must be interpreted in the proper context. A diverse array of other diseases, ranging from atherosclerosis to vasospasm to pheochromocytoma, may mimic the angiographic appearance of vasculitis. Systemic vasculitis can also be mimicked by two or more common medical problems or treatment complications occurring simultaneously in the same patient. Finally, high on the differential diagnosis of any individual form of vasculitis are other forms of vasculitis. For example, digital ischemia and splinter hemorrhages may be secondary to idiopathic polyarteritis nodosa. They may also be caused by polyarteritis nodosa associated with hepatitis B viral infection, granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis, microscopic polyangiitis, cryoglobulinemia, Buerger disease, or some other form of vasculitis. Because the appropriate interventions for these conditions vary widely, careful distinction among these potential etiologies is essential.

TABLE 249-5 MAJOR DISEASE CATEGORIES IN THE DIFFERENTIAL DIAGNOSIS OF VASCULITIDES

Other forms of vasculitis
Simultaneous occurrence of common medical problems in the same patient
Infections
Bacterial, viral, mycobacterial, fungal
Occlusive processes
Hypercoagulable states
Livedoid vasculopathy (atrophie blanche)
Atheroembolic disease
Malignant neoplasms
Lymphoma (including lymphomatoid granulomatosis)
Castleman disease
Amyloidosis
Paraproteinemias
Connective tissue disorders
Systemic lupus erythematosus, mixed connective tissue disease
Systemic sclerosis
Rheumatoid arthritis
Miscellaneous
Atrial myxoma
Calciphylaxis
Fibromuscular dysplasia
Neutrophilic dermatoses
Pyoderma gangrenosum
Sarcoidosis
Reversible cerebral vasoconstriction syndrome

TREATMENT

General Approach

The intensity of treatment in patients with vasculitis must be guided by the degree of disease activity. Specifically, the treatment of vasculitis should be predicated not only on abnormal laboratory test results but also on clear evidence of active disease. In addition, the intensity of treatment must be adapted to the type of vasculitis.

Conventional therapies such as glucocorticoids, immunomodulating agents, and cytotoxic drugs induce remissions and control most cases of vasculitis. Moreover, in some cases—a variable percentage, depending on the type of vasculitis—the disease is curable. Whereas giant cell arteritis usually responds to high doses of glucocorticoids, granulomatosis with polyangiitis nearly always requires an additional agent (e.g., rituximab, cyclophosphamide, or methotrexate) for disease control. Rituximab (500 mg or 1 g every 4 to 6 months, at least until lengthy periods of disease control are established) is replacing cyclophosphamide as the drug of choice for some forms of vasculitis, particularly in patients with antibody-associated vasculitis who demonstrate a tendency to flare. In contrast, despite the dramatic fashion in which they sometimes present, most cases of IgA vasculitis and cutaneous leukocytoclastic angiitis require no immunosuppressive treatment at all.

Unfortunately, the treatments of vasculitis have enormous potential for toxicity, especially higher doses of glucocorticoids, which remain a cornerstone for treating many forms of systemic vasculitis. When these higher doses are tapered to lower doses or discontinued, vasculitis often recrudesces. Throughout the period of their use, patients should be monitored for glucocorticoid toxicity (Chapter 28), and appropriate measures must be taken to reduce their potential adverse outcomes. For other forms of treatment, regular monitoring of patients' bone marrow, renal, and hepatic function is essential to avoid treatment-induced toxicity. Prophylaxis against opportunistic infections, particularly *Pneumocystis* pneumonia (Chapter 313), is an important part of many vasculitis treatment regimens.

A common error is treating patients for too long with high doses of immunosuppressive agents. The most appropriate use of medications such as glucocorticoids and cyclophosphamide is to induce remission as quickly as possible with early, aggressive treatment regimens and then to convert patients to safer treatments for the maintenance of remission. During the tapering of immunosuppressive medications, however, disease flares are common in many forms of vasculitis.

PROGNOSIS

Assuming that the diagnosis is made before the patient has become catastrophically ill, the prognosis in systemic vasculitis is determined largely by the answers to four questions:

1. Was the diagnosis established before the occurrence of major irreversible organ damage?
2. Was aggressive (but appropriately dosed) treatment begun in a timely fashion?
3. Was the patient carefully monitored during treatment, and were specific steps taken to avoid drug-induced toxicity (e.g., opportunistic infection)?
4. Were the potentially toxic medications that induced remission stopped at an appropriate juncture and replaced with less dangerous medications (or was treatment stopped altogether)?

For most forms of vasculitis, the factors that determine long-term drug-free remissions remain poorly understood. The likelihood of achieving sustained remissions after discontinuation of all medications (or cures) varies according to the specific type of vasculitis.

SPECIFIC VASCULITIDES

Large-Vessel Vasculitides

TAKAYASU ARTERITIS

Takayasu arteritis (Chapter 63) affects the aorta and its major branches. In contrast to atherosclerosis, which is characterized by focal irregular lesions, the lesions of Takayasu arteritis are long, smooth, tapered stenoses (Fig. 249-1). The most commonly involved arteries are the subclavian and innominate arteries.[2] Takayasu arteritis has been termed "pulseless disease" because of its ability to obliterate peripheral pulses (particularly in the upper extremities). Exuberant collateral circulation develops over time in response to the gradual narrowing of major arteries, thereby making the loss of digits or limbs from ischemia extremely rare. The extensive development of collateral circulation usually renders unnecessary any attempts to revascularize stenoses of primary aortic branches, such as the subclavian artery. The pulmonary circulation is involved in approximately 50% of cases of Takayasu arteritis.

Patients with severe narrowing of the aortic arch vessels supplying the head may develop Takayasu retinopathy, which is a hypotensive retinopathy that leads to neovascularization. This complication is particularly difficult to diagnose because vascular narrowings of large arteries to the arms and legs often lead to underestimations of the true central aortic pressure. Takayasu arteritis involvement of the ascending aorta may lead to aortic dilation, aortic regurgitation, aneurysms, and aortic rupture.

TREATMENT AND PROGNOSIS

For patients with marked symptoms and signs of an inflammatory phase, glucocorticoids (prednisone 1 mg/kg/day) are usually effective in controlling the disease.[3] The toxicity of high doses of glucocorticoids in young women, however, should stimulate the early consideration of alternative agents. IL-6 inhibition with tocilizumab (either intravenously at 8 mg/kg each month or subcutaneously at 162 mg each week) can allow the prednisone dose to be tapered to low doses (10 mg daily or less) within 3 months and ultimately be discontinued altogether,[A1,A2] if possible. The optimal duration of tocilizumab in Takayasu arteritis is uncertain. Consideration may be given to tapering (to either 4 mg/kg intravenously each month or 162 mg subcutaneously every other week) after 1 year. Large-vessel imaging may be useful in guiding decisions regarding the duration of therapy. About 50% of patients will relapse within 10 years, so some Takayasu arteritis patients may require chronic treatment with tocilizumab plus (possibly) low-dose glucocorticoids.

GIANT CELL ARTERITIS

Giant cell arteritis, which is the other primary form of vasculitis that involves arteries far larger than vasculitides of any other category, is discussed in Chapter 250.

Medium-Vessel Vasculitides

POLYARTERITIS NODOSA

Most polyarteritis nodosa is idiopathic, but about 15% of cases are linked to chronic hepatitis B viral infection (Chapter 135). Polyarteritis nodosa has a striking predilection for certain organs, particularly the skin, peripheral nerves, gastrointestinal tract, and kidneys.[4] This disease usually begins with nonspecific symptoms such as malaise, fatigue, fever, myalgias, and arthralgias. Overt signs of vasculitis may not occur until weeks or months after onset of the first symptoms. Skin lesions of polyarteritis nodosa include livedo reticularis, subcutaneous nodules, ulcers, and digital gangrene. A majority of patients with polyarteritis nodosa (>80% in some series) have vasculitic neuropathy, typically in the pattern of a mononeuritis multiplex.

The classic gastrointestinal manifestation of polyarteritis nodosa is "intestinal angina," the occurrence of postprandial abdominal pain. Polyarteritis nodosa can also affect individual gastrointestinal tract organs such as the gallbladder or appendix, presenting as cholecystitis or appendicitis, respectively. The typical renal manifestation of polyarteritis nodosa is vasculitic involvement of the medium-sized intrarenal arteries, thereby leading to renin-mediated hypertension and renal infarctions. Cardiac lesions, which usually remain subclinical, may lead to myocardial infarction or heart failure. Polyarteritis nodosa usually spares the lungs.

The diagnosis of polyarteritis nodosa requires either a tissue biopsy or an angiogram that demonstrates microaneurysms (Fig. 249-2).[5] Simultaneous nerve and muscle biopsies (e.g., sural nerve and gastrocnemius muscle) are of high yield when a vasculitic neuropathy is suspected. Symptoms suggestive of a neuropathy can be confirmed by electrodiagnostic studies that demonstrate a sensorimotor axonal neuropathy, often in a mononeuritis multiplex pattern. The pathologic changes in polyarteritis nodosa are limited to the arterial circulation, and the lesions are segmental, favoring the branch points of arteries. In gross pathologic specimens, aneurysmal bulges of the arterial wall may be visible. Histologic sections reveal infiltration and destruction of the blood vessel wall by inflammatory cells, accompanied by fibrinoid necrosis. Granulomatous inflammation is absent.

TREATMENT AND PROGNOSIS

For polyarteritis nodosa that is linked to chronic hepatitis B viral infection, antiviral therapy (see Chapters 134 and 135) combined with plasma exchange and short-term (2-week) courses of glucocorticoids are recommended. Patients with idiopathic polyarteritis nodosa and multiorgan involvement require high-dose glucocorticoid treatment initially (prednisone 1 mg/kg, up to 60 to 80 mg, daily for 4 weeks) followed by a gradual reduction to 10 mg daily or less. Approximately half of patients with idiopathic polyarteritis nodosa achieve remissions or cures with these high doses of glucocorticoids alone. Severe cases of multiorgan disease, particularly vasculitic neuropathy, should be treated with cyclophosphamide (2 mg/kg/day, adjusted for renal dysfunction) as well.[6] For patients with idiopathic polyarteritis nodosa limited to the skin or with refractory disease, tumor necrosis factor inhibitors (e.g., infliximab 5 mg/kg intravenously at 0, 2, and 6 weeks and then every 6 weeks) may be effective glucocorticoid-sparing agents. Most patients with either hepatitis B virus–associated or idiopathic polyarteritis nodosa ultimately achieve cures of their disease.

KAWASAKI DISEASE

Kawasaki disease, which is also known as mucocutaneous lymph node syndrome, occurs exclusively in young children. Cases typically follow an otherwise unremarkable infection, although cases were also reported after infection with the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) as part of a multisystem inflammatory syndrome.[7] In its acuity and severity, Kawasaki disease resembles toxic shock syndrome (Chapters 267 and 269) and scarlet fever (Chapter 269). Features of Kawasaki disease include high fevers, cervical adenopathy, conjunctival congestion, buccal erythema, prominence of the tongue papillae ("strawberry tongue"), a polymorphous truncal rash, erythema of the palms and soles, and desquamation of skin from the fingertips occurring days to weeks into the illness.[8]

In a small number of patients with Kawasaki disease, panvasculitis in the coronary vessels leads to narrowing of the vessel lumen by the migration of myointimal cells from the media through the fragmented internal elastic lamina. Direct complications include aneurysmal dilation and thrombosis of the coronary arteries, thereby leading to myocardial infarction.

TREATMENT AND PROGNOSIS

The recommended therapeutic regimen in Kawasaki disease is the combination of intravenous immune globulin (IVIG; 400 mg/kg/day on 4 consecutive days) and acetylsalicylic acid (100 mg/kg/day, lowered to 3 to 5 mg/kg/day after resolution of the fever). IVIG prevents the formation of coronary aneurysms in most cases.[9] For patients who are predicted to be unresponsive to IVIG, the combination of IVIG plus cyclosporine (5 mg/kg for 5 days) is better than IVIG alone.[A3] Glucocorticoids are reserved for salvage therapy under expert guidance in patients whose treatment with IVIG and acetylsalicylic acid has failed.[A4]

About 1 to 2% of patients with Kawasaki disease die during the acute illness. Late mortality from myocardial infarction may occur from the thrombosis of coronary artery aneurysms formed during the initial inflammatory stage. Such myocardial infarctions have been reported in middle-aged individuals who had febrile illnesses consistent with Kawasaki disease in childhood.

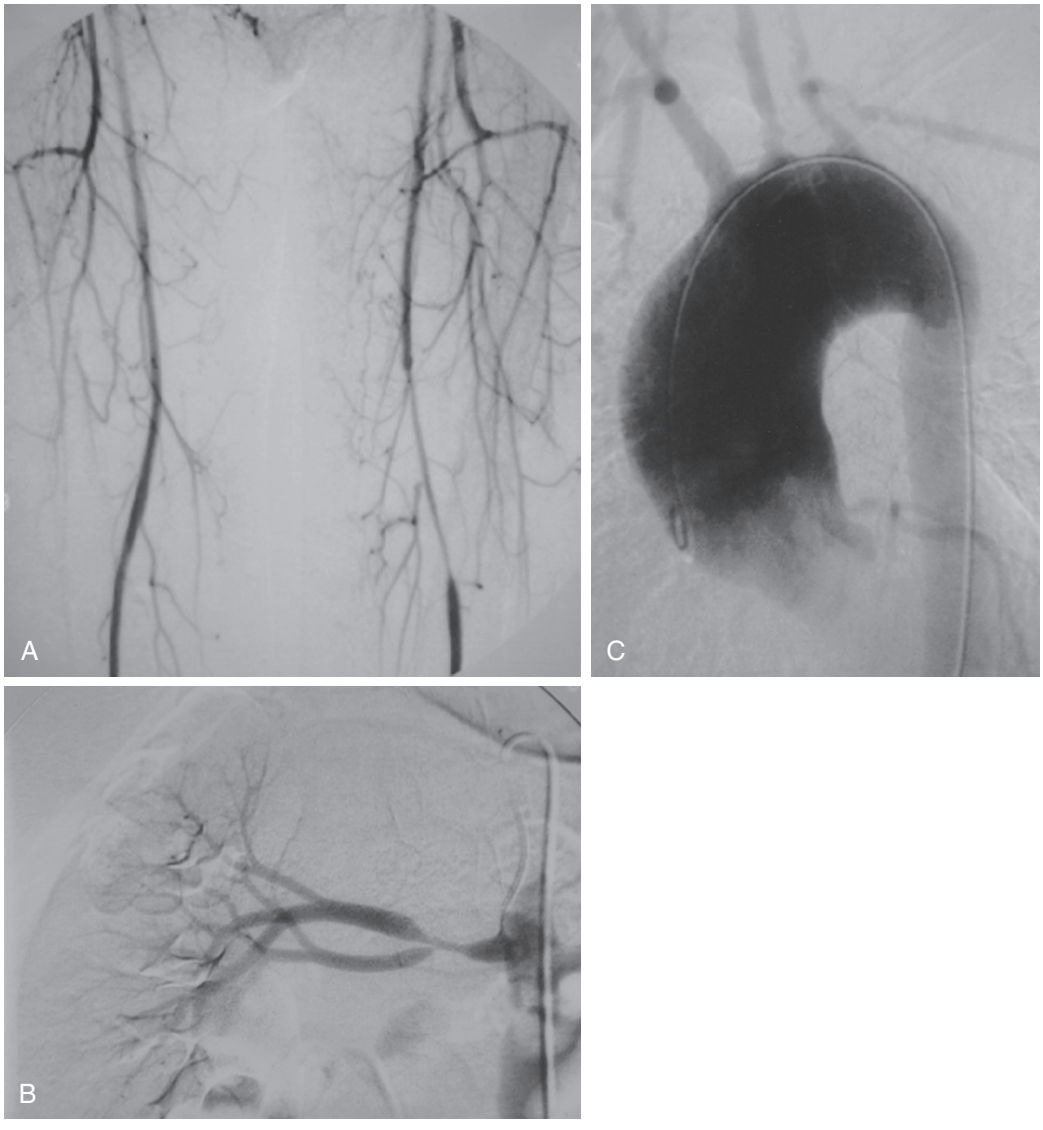

FIGURE 249-1. Large-vessel disease in Takayasu arteritis. Long, smooth tapering in the left common femoral artery (**A**) and the right renal artery (**B**). Dilation of the ascending aorta (**C**). Aortic regurgitation necessitated an aortic valve replacement and replacement of the ascending aorta with a Gore-Tex graft.

BUERGER DISEASE

Buerger disease, also known as thromboangiitis obliterans, is discussed in detail in Chapter 66.

SMALL-VESSEL VASCULITIDES

ANTINEUTROPHIL CYTOPLASMIC ANTIBODY–ASSOCIATED VASCULITIDES

Granulomatosis with Polyangiitis

Classic granulomatosis with polyangiitis involves the upper respiratory tract, lungs, and kidneys. Distinctive features may also occur in the eyes, ears, and other organs. The three pathology hallmarks of granulomatosis with polyangiitis are (1) granulomatous inflammation in the upper or lower respiratory tract, (2) necrotizing vasculitis affecting arteries or veins, and (3) segmental glomerulonephritis associated with necrosis and thrombosis of capillary loops, with or without granulomatous lesions.[10]

Approximately 90% of patients with granulomatosis with polyangiitis have nasal involvement, including crusting, bleeding, and obstruction. Cartilaginous inflammation may lead to nasal septal perforation and collapse of the nasal bridge ("saddle nose" deformity). Erosive sinus disease and subglottic stenosis (narrowing of the trachea just below the vocal cords) are highly characteristic.

Both conductive and sensorineural hearing loss can occur in granulomatosis with polyangiitis, though conductive lesions caused by middle ear disease are more common. Orbital masses ("pseudotumors" that develop behind the eye), scleritis, and peripheral ulcerative keratitis are the most dangerous ocular lesions. Episcleritis and conjunctivitis also occur. Uveitis is rare. The clinical manifestations in the lungs range from asymptomatic nodules to fulminant alveolar hemorrhage. The most common radiographic findings are pulmonary infiltrates, nodules, and cavitary lesions. Large-airway disease leading to bronchial narrowing is a challenging diagnosis to establish because patients present with few symptoms until advanced disease is present.

The clinical presentation of renal disease in granulomatosis with polyangiitis is usually rapidly progressive glomerulonephritis (Chapter 107) with hematuria, red blood cell casts, and proteinuria (usually non-nephrotic). Without appropriate therapy, end-stage renal disease may ensue within weeks.

Sixty percent of patients with granulomatosis with polyangiitis have musculoskeletal symptoms during their disease course. The presenting complaint is frequently arthralgias or an oligoarthritis that is migratory in nature. Skin lesions include the full panoply of lesions associated with cutaneous vasculitis, including purpura (Fig. 249-3). Cutaneous nodules over the extensor surfaces of joints, particularly the elbow, may mimic rheumatoid nodules. These lesions are known as cutaneous extravascular necrotizing granulomata or Churg-Strauss lesions. Meningeal inflammation, which presents with headaches, cranial neuropathies, and a clinical picture compatible with chronic meningitis, is perhaps the most common central nervous system (CNS) manifestation of granulomatosis with polyangiitis. Mononeuritis multiplex may affect the peripheral nervous system.

Granulomatosis with polyangiitis is the prototype of conditions associated with ANCA.[11] Approximately 75 to 80% of patients have antibodies directed

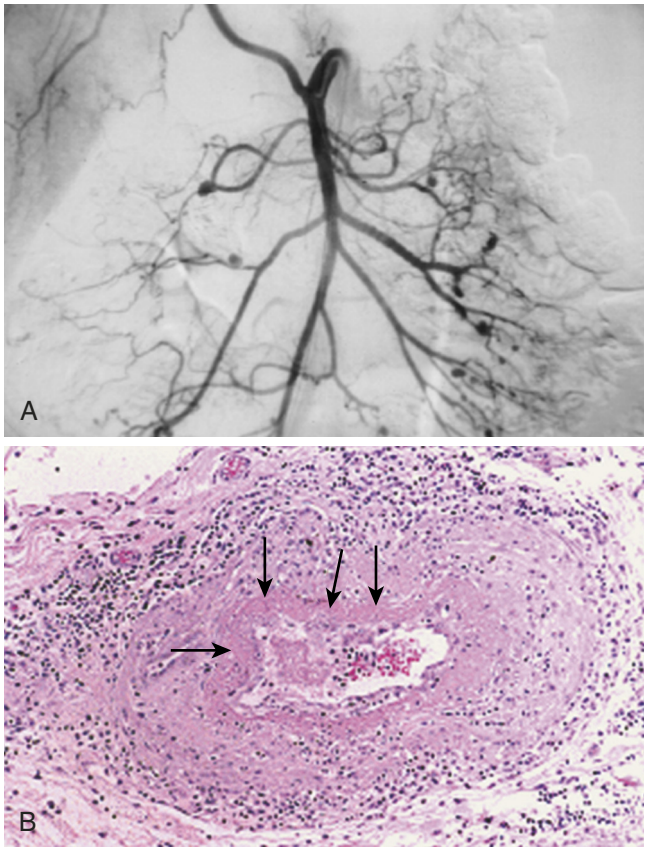

FIGURE 249-2. **Vasculitis of medium-sized arteries in polyarteritis nodosa. A,** Mesenteric angiogram showing numerous aneurysms in medium-sized arteries. **B,** Fibrinoid necrosis (*arrows*) in a jejunal artery from a patient who required surgical resection of necrotic bowel.

against proteinase 3 (PR3), which lead to positive cytoplasmic (C-ANCA) staining on immunofluorescence testing of serum against human neutrophils. In another 10 to 15% of patients, antibodies directed against myeloperoxidase (MPO) cause perinuclear staining on immunofluorescence. An ANCA-negative assay sample does not exclude granulomatosis with polyangiitis, because a substantial minority of patients are ANCA-negative. ANCA titers do not correlate precisely with disease activity and, indeed, should generally not be used as the sole guide to treatment.

TREATMENT AND PROGNOSIS

Manifestations of granulomatosis with polyangiitis can constitute immediate threats either to the function of a vital organ or to the patient's life and require urgent treatment.[12,13] For patients with polyangiitis, rituximab (375 mg/m^2 weekly times four) is at least as effective as a combination of cyclophosphamide (2 mg/kg orally daily) plus glucocorticoids and is associated with fewer adverse effects.[A5] Rituximab appears to be more effective for patients who have antibody-associated vasculitis and present with disease flares. An alternative dosing regimen of rituximab 1 g times two separated by 2 weeks may also be effective.[14] After initial therapy, extended rituximab therapy every 6 months can yield sustained remission.[A6] A reduced prednisone dose (0.5 mg/kg orally) appears to be as efficacious as higher doses, and plasma exchange is of no incremental value.[A7] Avacopan (30 mg orally twice daily), an oral complement inhibitor that blocks the C5a receptor, can be used to reduce glucocorticoid toxicity in ANCA-associated vasculitis by substantially decreasing the quantity of glucocorticoids required to induce remission induction in patients with severe disease.[A8] Limited forms of granulomatosis with polyangiitis may respond to the combination of methotrexate (up to 25 mg/week) and glucocorticoids, but rituximab is now often used in this setting as well. Rituximab (e.g., 500 mg every 6 months) is more effective than azathioprine for maintaining remission in patients who demonstrate a tendency to flare.

The prognosis of patients who achieve and maintain disease remissions, with or without ongoing remission maintenance therapy, is good. Toxicities from glucocorticoid treatment may affect quality of life and even longevity.

FIGURE 249-3. **Cutaneous small-vessel vasculitis showing palpable purpuric lesions with necrosis and crusting.**

Microscopic Polyangiitis

Microscopic polyangiitis is characterized by nongranulomatous necrotizing vasculitis with few or no immune deposits, involvement of small (and possibly medium-sized) blood vessels in the arterial or venous circulation, and tropism for the kidneys and lungs.[15] Many cases of small-vessel vasculitis once regarded as polyarteritis nodosa are now classified more properly as microscopic polyangiitis.

In contrast to polyarteritis nodosa, which is an ANCA-negative disorder, 70% of microscopic polyangiitis patients are ANCA-positive, so microscopic polyangiitis is considered to be a form of antibody-associated vasculitis. The ANCAs in microscopic polyangiitis are usually directed against myeloperoxidase, thereby leading to a perinuclear pattern of staining on immunofluorescence testing (P-ANCA). Microscopic polyangiitis is not characterized by granulomatous inflammation, and upper respiratory tract symptoms, if present at all, are much milder than in granulomatosis with polyangiitis.

TREATMENT AND PROGNOSIS

The approach to the treatment of microscopic polyangiitis is similar to the treatment of granulomatosis with polyangiitis, with the combination of rituximab and glucocorticoids as the treatment regimen of choice for most patients. Avacopan can also be administered in this setting in the interest of reducing glucocorticoid use and toxicity, though it does not supplant glucocorticoid use entirely.

The prognosis in microscopic polyangiitis is often dictated by disease-related damage present at diagnosis. For example, renal dysfunction can persist, even though remission is achieved in the great majority of patients.

Eosinophilic Granulomatosis with Polyangiitis

Eosinophilic granulomatosis with polyangiitis is an eosinophil-rich form of granulomatous inflammation that involves the respiratory tract and other organs. The disease is associated with necrotizing vasculitis of small to medium-sized vessels. Two hallmarks of eosinophilic granulomatosis with polyangiitis are asthma and eosinophilia, and several phases are described:[16,17]

- A prodromal phase characterized by the presence of allergic disease (typically asthma or allergic rhinitis), which may persist months to many years

- An eosinophilia–tissue infiltration phase, in which remarkably high peripheral eosinophilia may occur, and tissue infiltration by eosinophils is observed in the lung, gastrointestinal tract, and other tissues
- A vasculitic phase, in which systemic necrotizing vasculitis afflicts a wide range of organs, ranging from the heart and lungs to peripheral nerves and skin

Approximately 50% of cases of eosinophilic granulomatosis with polyangiitis are associated with ANCA, usually directed against myeloperoxidase, but the percentage may be higher among untreated patients.

TREATMENT AND PROGNOSIS

Patients with mild disease may be treated with prednisone. The addition of mepolizumab 300 mg subcutaneously each month has an important glucocorticoid-sparing role.[A9] Patients with evidence of neurologic, cardiac, renal, or gastrointestinal involvement should be treated with cyclophosphamide or rituximab[18] as in granulomatosis with polyangiitis, in addition to glucocorticoids and mepolizumab.

Although clinical remissions are obtained in more than 90% of patients with eosinophilic granulomatosis with polyangiitis, the majority of patients are unable to discontinue glucocorticoids entirely (primarily because of asthmatic symptoms), and disease recurrences are seen in 25%. In most cases, relapses are heralded by the return of eosinophilia.

IMMUNE COMPLEX–MEDIATED VASCULITIDES

Anti–Glomerular Basement Membrane Disease

Anti–glomerular basement membrane (anti-GBM) disease is a vasculitis that affects glomerular capillaries, pulmonary capillaries, or both, accompanied by the deposition of anti–basement membrane autoantibodies within basement membranes. Anti-glomerular basement membrane disease is discussed in detail in Chapter 107.

Immunoglobulin A Vasculitis/Henoch-Schönlein Purpura

IgA vasculitis is characterized by nonthrombocytopenic purpura, arthritis, abdominal pain, and glomerulonephritis. The histopathologic findings are those of a leukocytoclastic vasculitis with IgA deposition. IgA vasculitis can develop at any age, but 80 to 90% of the cases occur in children. Although the cause is unknown, the disease's seasonal variation and the fact that two thirds of patients experience an antecedent acute upper respiratory illness suggest an infectious trigger in the majority of cases. The diagnosis of IgA vasculitis can be confirmed only by demonstration of IgA deposition within and around blood vessel walls.

The classic patient presents with the acute onset of fever, palpable purpura on the lower extremities and buttocks, abdominal pain, arthritis, and hematuria.[19] The clinician must be alert to the possibility of IgA vasculitis even when only parts of the syndrome are present.

TREATMENT

Glucocorticoids ameliorate the gastrointestinal, joint, and skin symptoms in many cases, but some patients respond surprisingly poorly to conventional doses of glucocorticoids, even in doses on the order of 40 to 60 mg/day. Anecdotal evidence suggests that pulse glucocorticoids (e.g., methylprednisolone 500 to 1000 mg/day times three doses) may abort persistent bouts of IgA vasculitis. The efficacy of glucocorticoids in the glomerulonephritis associated with this condition is controversial. Uncontrolled studies suggest that methylprednisolone pulses (1 g/day for three doses) followed by oral prednisone combined with azathioprine or mycophenolate mofetil may be useful in severe glomerulonephritis. Most patients, especially children, have a self-limited disease that persists for an average of 4 weeks.

Hypocomplementemic Urticarial Vasculitis

At least three subtypes of urticarial vasculitis are defined: (1) normocomplementemic, a form that is generally idiopathic and benign (and may be viewed as a manifestation of cutaneous leukocytoclastic angiitis); (2) hypocomplementemic, a form that is often associated with a systemic inflammatory disease; and (3) hypocomplementemic urticarial vasculitis syndrome, a potentially severe condition usually associated with autoantibodies to the collagen-like region of C1q.[20] Most patients with the hypocomplementemic subtype have an underlying systemic disorder, such as systemic lupus erythematosus (Chapter 245) or Sjögren syndrome (Chapter 247). Many patients who have hypocomplementemic urticarial vasculitis syndrome have C1q "precipitins," which are IgG autoantibodies to the collagen-like region of C1q and which trigger the classical pathway of complement activation (Chapter 37). The role of anti-C1q antibodies in disease pathogenesis remains unclear.

The lesions of urticarial vasculitis must be distinguished from the far more common chronic idiopathic urticaria (Chapters 232 and 407). Unlike idiopathic urticaria, the lesions of urticarial vasculitis persist for more than 48 hours, often have a purpuric component (i.e., they do not blanch), and resolve with postinflammatory hyperpigmentation. In urticarial vasculitis, lesions associated with vasculitis are often accompanied by stinging or burning.

On biopsy, urticarial vasculitis affects the capillaries and postcapillary venules, with leukocytoclastic vasculitis on light microscopy. Direct immunofluorescence studies reveal both immunoglobulin and complement deposition in or around blood vessels of the upper dermis or the dermoepidermal junction.

TREATMENT

Patients with urticarial vasculitis whose serum complement levels remain normal during attacks often have self-limited disease and require little therapy. Other cases, especially hypocomplementemic urticarial vasculitis, may cause life-threatening involvement of the lungs or other organs and require periods of intensive immunosuppression. Treatment decisions, including glucocorticoids, biologic agents, and cytotoxic drugs given under expert supervision, must be individualized according to the patient's clinical status.

Cryoglobulinemia

Cryoglobulins are antibodies that precipitate from serum under conditions of cold and resolubilize on rewarming. Cryoglobulins are classified into types I, II, and III on the basis of whether monoclonality and rheumatoid factor activity (the ability to bind to the Fc portion of IgG) are present. Type I cryoglobulins, which are monoclonal but lack rheumatoid factor activity, are associated with certain hematopoietic malignant neoplasms (e.g., multiple myeloma; Chapter 173) and often lead to hyperviscosity rather than to vasculitis. In contrast, type II and type III cryoglobulins may be associated with systemic vasculitis involving small and often medium-sized blood vessels. Vasculitis results from the deposition of cryoglobulin-containing immune complexes within blood vessel walls and the activation of complement.

Cryoglobulin types II and III are termed *mixed cryoglobulins* because they consist of complexes of both IgG and IgM antibodies. The IgM components in both type II and type III cryoglobulinemia possess rheumatoid factor activity (i.e., assays for rheumatoid factor are positive, thereby indicating binding of the IgM antibody to the Fc portion of IgG). Whereas the IgM component in type II cryoglobulin is monoclonal, the IgM in type III cryoglobulin is polyclonal. Ninety percent of patients with vasculitis secondary to mixed cryoglobulins are hypocomplementemic, with C4 levels characteristically more depressed than C3. Infection with hepatitis C virus (Chapters 134 and 135) accounts for at least 80% of the vasculitis cases associated with mixed cryoglobulins.

TREATMENT

The optimal therapy for most cases of cryoglobulinemic vasculitis is successful treatment of the underlying hepatitis C viral infection (Chapters 134 and 135). For cryoglobulinemic patients with relatively mild disease (e.g., frequent purpuric lesions, shallow cutaneous ulcers), short courses of prednisone (e.g., 20 mg/day) followed by the institution of effective therapy for hepatitis C virus may be sufficient. For patients with severe cutaneous ulcers, mononeuritis multiplex, glomerulonephritis, or other manifestations of severe disease, treatment with glucocorticoids, rituximab (similar to the way that granulomatosis with polyangiitis is treated),[21] and possibly a short course of plasma exchange may be indicated.

VARIABLE-VESSEL VASCULITIDES

The variable-vessel vasculitides have no predominant type of vessel involved but rather can affect vessels of any size (small, medium, and large) and any type (arteries, veins, and capillaries).

COGAN SYNDROME

The combination of inflammatory eye disease and vestibuloauditory dysfunction is the sine qua non of Cogan syndrome.[22] In addition to inflammatory disease of the eyes and ears, up to 15% of patients with Cogan syndrome have vasculitis involving medium-sized to large blood vessels. Although the ocular manifestations vary, the classic presentation is the combination of interstitial keratitis and sensorineural hearing loss. Cogan syndrome may appear first in either the eyes or the ears. Although intervals as long as 1 to 2 years have been described between the start of disease in one organ and the appearance of disease in the other, the time between disease manifestations in these organs is usually only a matter of months. Patients usually present with photophobia and blurry vision, sometimes accompanied simultaneously by auditory or vestibular dysfunction. The vascular disease associated with Cogan syndrome remains poorly described but typically involves the primary branches of the thoracic or abdominal aorta.

TREATMENT

Rapidly progressive sensorineural hearing loss (Chapter 396) requires early and aggressive therapy with high doses of systemic glucocorticoids (e.g., prednisone 60 mg/day). Some otolaryngologists also give intratympanic injections of glucocorticoids. Cyclophosphamide, mycophenolate mofetil, and biologic agents such as tumor necrosis inhibitors or rituximab can be considered under expert guidance for patients with suboptimal responses to glucocorticoids who still have salvageable hearing. Nevertheless, attempts at treatment are begun too late in some patients, and it is important to realize when the risk of further immunosuppression outstrips the likelihood of long-term benefit. Many Cogan syndrome patients become candidates for cochlear implants (Chapter 396).

BEHÇET SYNDROME

Behçet syndrome may affect small, medium, and large vessels in either the venous or the arterial circulation.[23] The most typical lesions are mucocutaneous, thereby reflecting the involvement of small blood vessels. The triad of recurrent mouth ulcers, genital ulcers, and eye inflammation is the classic presentation. The criteria for diagnosis consist of one required manifestation—recurrent oral ulceration—plus at least two of the following: recurrent genital ulceration, characteristic eye or skin lesions, or a pathergy reaction, which is the development of pustules at the sites of sterile needle pricks. However, the spectrum of Behçet syndrome encompasses many manifestations not included in these criteria. In addition, oral ulcers are not invariably the first disease manifestation, so the diagnosis of Behçet syndrome must be considered in the occurrence of disease features otherwise highly characteristic (e.g., bilateral panuveitis).

Large-vessel complications of Behçet syndrome may include aneurysms in the pulmonary and systemic arterial systems. Venous complications include thromboses of the deep venous system, vena cava, portohepatic vein, and cerebral sinus. The pathergy reaction is seen in many patients but particularly in persons of Turkish origin. The arthritis of Behçet syndrome is a nondeforming, oligoarticular, asymmetrical arthritis of large joints. Gastrointestinal lesions in Behçet syndrome typically consist of ulcerations of the distal ileum or cecum. Crohn disease (Chapter 127), which can cause genital ulcers as well as gastrointestinal disease, may be particularly difficult to distinguish from Behçet syndrome.

TREATMENT AND PROGNOSIS

Low-dose glucocorticoids (e.g., prednisone 20 mg/day) are effective for intransigent mucocutaneous disease and may have a better side effect profile than other medications used for this purpose (e.g., thalidomide 100 mg/day). Intermittent courses of glucocorticoids during periods of particular mucocutaneous disease activity may be sufficient for patients with mild disease.[24] Apremilast, an oral phosphodiesterase 4 inhibitor (at 30 mg twice daily for 12 weeks), is effective for treating oral ulcers.[A10] Colchicine (0.6 mg daily or twice daily) is often considered for mucocutaneous disease, but its true efficacy remains uncertain, and it is not appropriate for the treatment of major organ involvement.

Severe disease in any organ system always requires initial therapy with high doses of prednisone (e.g., 1 mg/kg/day). However, TNF inhibition with infliximab (5 mg/kg IV every 4 to 6 weeks) or adalimumab (40 mg every other week) is the treatment of choice for patients with the most severe forms of uveitis or meningoencephalitis. TNF inhibition, which is highly effective and usually well tolerated, is typically continued indefinitely in patients who respond to this therapy. Patients' prognosis is determined by disease-related damage incurred before the establishment of effective therapy as well as the tolerability of treatment long-term.

SELECTED SINGLE-ORGAN VASCULITIDES

Single-organ vasculitis is defined as vasculitis within the vessels of any type or size of a single organ in the absence of any features (e.g., ANCA) to suggest one of the systemic forms of vasculitis.

CUTANEOUS LEUKOCYTOCLASTIC ANGIITIS

Cutaneous leukocytoclastic angiitis has also been termed *hypersensitivity vasculitis*. Cutaneous leukocytoclastic angiitis is the preferred name because no hypersensitivity or allergy is evident in many cases.[25] Histories of exposure to new medications or to infections may be elicited. An immune complex deposition is central to the pathophysiologic process. Although cutaneous leukocytoclastic angiitis is occasionally associated with synovitis, other signs of systemic involvement are absent.

The skin lesions in cutaneous leukocytoclastic angiitis occur in "crops" of palpable purpura (see Figs. 406-5 and 406-7) coinciding with some period of elapsed time following exposure to the inciting antigen. The usual time between the exposure and the onset of clinically evident vasculitis is 10 to 14 days. The lesions typically occur first in dependent regions, such as on the lower extremities or buttocks. The rash may be asymptomatic but is usually accompanied by burning or tingling sensations.

TREATMENT AND PROGNOSIS

Several approaches to treatment are reasonable. First is watchful waiting, since it is not clear that immunosuppression is either necessary or helpful. Moreover, attempts to treat vasospasm with calcium-channel blockers may lead to a vascular steal phenomenon, thereby potentially causing harm. Second, because it is frequently difficult to do nothing for a patient with possibly serious CNS disease, calcium-channel blockers (e.g., nifedipine 30 mg three times daily) may be tried. Third, because of the frequent diagnostic uncertainty at the time of presentation, some clinicians opt to treat empirically with glucocorticoids (prednisone 1 mg/kg/day) for 1 month, followed by a taper over several weeks. Fourth, combinations of calcium-channel blockers and glucocorticoids are also reasonable. Cytotoxic therapy is not indicated.

VASCULITIS OF THE CENTRAL NERVOUS SYSTEM

CNS vasculitis[26] includes two major categories of disease, one of which is not a true vasculitis. These conditions are primary angiitis of the CNS (PACNS) and reversible cerebral vasoconstriction syndrome (RCVS). The clinical, radiologic, and pathologic characteristics of these two conditions vary dramatically (Table 249-6).

Primary Angiitis of the Central Nervous System

Primary angiitis of the central nervous system typically develops in a subacute fashion, with the evolution of multifocal strokes, encephalopathy, headache, and other clinical features over months. Headache is often the first symptom. As the condition progresses, most patients develop lethargy, confusion, and memory loss. Some patients develop multifocal strokes, seizures, evidence of increased intracranial pressure, or myelopathy. The results of routine laboratory tests (e.g., erythrocyte sedimentation rate) are often normal in PACNS. Lumbar puncture, which should be performed in all patients in whom the diagnosis is considered seriously, demonstrates abnormalities of the cerebrospinal fluid in approximately 80% of cases, usually a modest monocytosis and elevated protein. Although the findings on lumbar puncture are nonspecific, a normal lumbar puncture argues against primary angiitis of the central nervous system, and the procedure frequently identifies important mimickers such as infection (Chapters 381, 382, and 383) or malignancy (Chapter 175).

Magnetic resonance imaging (MRI) is the critical imaging modality. Because of the subacute nature of the disorder, MRI studies reveal multifocal CNS infarctions in most cases. Strokes, hemorrhagic lesions, and mass lesions typically occur in more than one vascular territory. A normal brain MRI argues strongly against the diagnosis of primary angiitis of the central nervous system. Angiography is less helpful because the involved blood vessels are often too small to be resolved adequately, even by conventional angiography, so the false-negative rate of angiography is about 35%. Second, the "classic" angiographic string-of-beads abnormality, which is produced by segmental arterial narrowing alternating with dilations, is nonspecific and can be mimicked perfectly by a host of nonvasculitic conditions (the most common of which is reversible cerebral vasoconstriction syndrome). No angiographic pattern is pathognomonic for

TABLE 249-6 PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM VERSUS REVERSIBLE CEREBRAL VASOCONSTRICTION

	PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM (PACNS)	REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME (RCVS)
Female-to-male ratio	1 : 1	2-3 : 1
Onset	Subacute (weeks to months)	Sudden (seconds to minutes)
Headache	Insidious, dull	Thunderclap
Typical lumbar puncture findings	Abnormal in 50-80%: lymphocytic pleocytosis; elevated protein	Normal
Typical MRI findings	Multifocal subacute infarctions	Normal Watershed infarcts in minority
Typical angiogram findings	Normal in up to 40% of cases Abnormal angiographic features when present cannot be distinguished from RCVS	Multifocal stenoses/dilatations
Utility of brain biopsy	Reasonable sensitivity in appropriately selected patients Important for excluding disease mimickers	Little to no role Helpful if confusing clinical situation confounds differentiation from PACNS or PACNS mimickers

MRI = magnetic resonance imaging.

primary angiitis of the central nervous system, and there is a significant tendency to overdiagnose "vasculitis" on angiographic grounds alone. A normal brain MRI in the setting of an abnormal angiogram suggests reversible cerebral vasoconstriction syndrome, not primary angiitis of the central nervous system. When performed in appropriately selected patients whose history and radiologic studies suggest primary angiitis of the central nervous system, brain biopsy is associated with reasonable positive and negative predictive values and frequently identifies important mimickers.

TREATMENT

Prednisone (60 mg/day, sometimes preceded by 1 to 3 days of 1000 mg/day pulse methylprednisolone) and cyclophosphamide (2 mg/kg daily, adjusted for renal dysfunction and advanced age) are appropriate for treatment of patients who have abnormal findings on brain biopsy. Treatment courses of 6 to 12 months are recommended. Patients with primary angiitis of the central nervous system respond to treatment and may achieve treatment-free remissions, but residual neurologic dysfunction and adverse effects of treatment are common and sometimes severe.

Reversible Cerebral Vasoconstriction Syndrome

Reversible cerebral vasoconstriction syndrome is probably far more common than primary angiitis of the central nervous system. Overtreatment of patients with reversible cerebral vasoconstriction syndrome who are misdiagnosed as having primary angiitis of the central nervous system leads to substantial morbidity. Eighty percent of patients with reversible cerebral vasoconstriction syndrome are women.

A careful history is the most important part of the evaluation. In contrast to the subacute course that typifies primary angiitis of the central nervous system, reversible cerebral vasoconstriction syndrome usually begins in a more dramatic fashion with a "thunderclap" headache.[27] Neurologic signs are less severe in reversible cerebral vasoconstriction syndrome (e.g., encephalopathy is less common). Reversible cerebral vasoconstriction syndrome frequently occurs in the setting of precipitants associated with vasospasm, such as in the postpartum setting or following the use of vasoactive agents such as nasal decongestants and recreational drugs.

The lumbar puncture is usually normal in reversible cerebral vasoconstriction syndrome, and brain MRI usually does not show multifocal CNS infarctions, with the exception of watershed infarctions. The typical angiographic findings in reversible cerebral vasoconstriction syndrome—vascular narrowing and beading—are generally indistinguishable from those of primary angiitis of the central nervous system and conditions that mimic them. Multifocal vascular narrowing is particularly characteristic of reversible cerebral vasoconstriction syndrome. The most distinctive angiographic feature of reversible cerebral vasoconstriction syndrome is that the abnormalities are completely reversible, usually within 4 to 8 weeks, because the abnormalities are caused by vasospasm rather than true vasculitis. In the evaluation of patients with potential reversible cerebral vasoconstriction syndrome, a diagnostic strategy that can clinch the diagnosis is a follow-up angiogram 4 to 8 weeks later, when angiographic abnormalities will have resolved.

TREATMENT AND PROGNOSIS

Keys to the management of cutaneous leukocytoclastic angiitis include exclusion of any underlying form of vasculitis that may cause subclinical involvement of other organs and removal of any agent (e.g., a medication) that may have triggered the vasculitis. For patients in whom a precipitant can be identified, elimination of the offending agent usually leads to resolution of the vasculitis within days to weeks. The type, intensity, and duration of therapy for cutaneous leukocytoclastic angiitis are based on the degree of disease severity. Mild cases may be treated simply with leg elevation, H_1 antihistamines (Table 404-3), or low-dose prednisone (starting at 20 mg/day). For persistent disease not associated with cutaneous gangrene, colchicine (0.6 mg once or twice daily), hydroxychloroquine (200 mg twice daily), or dapsone (100 mg/day) may be tried. For severe cases, high doses of prednisone (e.g., 60 mg/day) are indicated to suppress inflammation quickly and prevent skin ulceration.

250 GIANT CELL ARTERITIS AND POLYMYALGIA RHEUMATICA

ROBERT SPIERA

DEFINITION

Polymyalgia rheumatica and giant cell arteritis, also called temporal arteritis, are companion systemic inflammatory disorders of unknown etiology that is propagated by antigen-driven, cell-mediated immune mechanisms that may be associated with specific genetic markers. These disorders represent a spectrum from severe proximal aches and pains and constitutional symptoms to an occlusive granulomatous vasculitis of medium and large vessels that can lead to permanent blindness or other organ and tissue damage. These disorders occur primarily in patients older than age 50 years, are more common in women than in men, and are highly responsive to corticosteroids.

EPIDEMIOLOGY

In the United States, the average annual incidence of polymyalgia rheumatica is 52.5 per 100,000 patients ages 50 years and older and increases with age. The prevalence is about 0.5 to 0.7%. Internationally, the frequency varies, with the highest rates occurring in the Scandinavian countries. The incidence and prevalence of giant cell arteritis are approximately one third those of polymyalgia rheumatica.

PATHOBIOLOGY

The etiology of polymyalgia rheumatica and giant cell arteritis are unknown, but both demonstrate familial aggregation and have a genetic association with human leukocyte antigen (HLA)-DR4 and a demonstrated sequence polymorphism encoded within the hypervariable region of the *HLA-DRβ1*04* gene. Infectious triggers of giant cell arteritis have been postulated. For example, some but not all studies have found varicella-zoster virus antigen in temporal artery biopsies of patients with giant cell arteritis.[1] Bacterial and viral DNA also has been demonstrated in the arterial wall of patients with giant cell arteritis using advanced DNA imaging techniques. Disease in genetically predisposed patients also may be triggered by endogenous antigens such as elastin, and the inflammatory manifestations are directed by specific patterns of cell-mediated, type 1 helper T cell (T_H1)-associated cytokines. The cytokine production by the mononuclear cells in the involved tissues appears to influence the clinical phenotype.

In the pathogenesis of giant cell arteritis, the adventitia is considered the immunologic center where toll-like receptors (TLRs) are highly expressed on dendritic cells and resident tissue macrophages. Macrophages and T lymphocytes enter the vessel wall through the vasa vasorum with the aid of adhesion molecules and come into contact with an inciting antigen. Activated CD4 cells produce interferon-γ that attracts macrophages to the arterial wall. Some of these macrophages fuse at the intima-media to form multinucleated giant cells. These cells produce vascular endothelial growth factor, which triggers neovascularization, both at the intima-media junction and at the level of the vasa vasorum. The subsequent immunologic events lead to a characteristic topography of mononuclear cells throughout the vessel wall. Products of the giant cells and macrophages at the intima-media junction include collagenase and nitric oxide, both of which probably contribute to tissue damage. The pathologic impact of cytokines leads not only to the characteristic medial damage but also to significant intimal hyperplasia that eventually, if it is not treated, may cause luminal narrowing and tissue ischemia.

In giant cell arteritis, a transmural (involving all layers of the vessel) inflammatory infiltrate, comprised of predominantly mononuclear cells and commonly with giant cells, is found in the superficial temporal arteries as well as in other large and medium-sized arteries. In elderly patients, fragmentation of the internal elastica is characteristic and helps differentiate this vascular lesion from that of atherosclerosis. Often, macrophages containing fragments of elastic tissue are found at the intima-media junction, which is the histologic center of the inflammatory process. Intimal proliferation may be prominent and lead to luminal narrowing. Damage to the elastica and loss of vascular smooth muscle cells likely contribute to the recognized increased risk of aneurysms later in the disease course.

In polymyalgia rheumatica, mononuclear cell inflammation can be found not only in the proximal joints, such as the shoulders, but also in the surrounding tendons, bursae, and soft tissues consistent with enthesitis. Although muscle pains may be present, no significant muscle inflammation is found.

CLINICAL MANIFESTATIONS

Polymyalgia rheumatica and giant cell arteritis are systemic inflammatory disorders that occur primarily in patients older than age 50 years, in women more than in men (2:1), and more commonly in Whites. Shared characteristics of the two disorders include significant cytokine-driven constitutional symptoms, such as fever, fatigue, and weight loss, as well as a markedly elevated erythrocyte sedimentation rate (ESR), anemia, and thrombocytosis.

Polymyalgia Rheumatica

The musculoskeletal hallmark of polymyalgia rheumatica is proximal, severe, and symmetrical morning and even day-long stiffness, soreness, and pain in the shoulders,[2] neck, and pelvic girdles. Fifty percent of patients with giant cell arteritis share this characteristic proximal pain syndrome. Carpal tunnel syndrome (Chapter 388) and hand and knee synovitis may be seen in patients with polymyalgia rheumatica, but the overall presentation remains predominantly proximal, as opposed to rheumatoid arthritis, in which distal synovitis dominates. Whereas patients with polymyalgia rheumatica may appear to have proximal muscle weakness, this finding is due to pain and not muscle inflammation (Table 250-1). Magnetic resonance imaging (MRI) and ultrasound studies in patients with polymyalgia rheumatica have confirmed the presence of inflammation of extra-articular synovial structures, in particular subacromial and subdeltoid bursae in the shoulders.

Giant Cell Arteritis

Specific signs and symptoms of giant cell arteritis are best appreciated in their anatomic and physiologic contexts. Giant cell arteritis preferentially affects certain blood vessels, including the branches of the external carotid artery, the ophthalmic artery and particularly its posterior ciliary branches, and the large arteries that arise from the aortic arch and abdominal aorta. Headache and scalp pain are probably the most frequent symptoms, occurring in 50 to 75% of patients. Headache is often the first manifestation of giant cell arteritis and is described as boring, severe, and constant, unresponsive to simple pain medications and persisting through the night. Classically, patients complain of persistent and prominent temporal headaches, but occipital pains can also occur. Ear, pinna, or parotid gland pain may occur secondary to involvement of the posterior auricular artery. Jaw claudication and pain due to masseter

INFLAMMATORY
Polymyalgia rheumatica: constitutional symptoms
Fever
Weight loss
Fatigue
Laboratory abnormalities
Hematologic: anemia, thrombocytosis
Elevated sedimentation rate, C-reactive protein
ISCHEMIC
Ocular
Diplopia
Amaurosis fugax
Fixed vision loss
Complete blindness
Cranial symptoms
Headache
Jaw claudication
Scalp tenderness
Scalp or lingual necrosis (rare)
Cerebrovascular accidents
Large vessel disease
Leg or arm claudication
Diminished pulses, blood pressure asymmetry
Aortic aneurysms
LATE COMPLICATIONS
Aortic aneurysms
Thoracic aorta
Abdominal aorta
Corticosteroid complications
Osteoporosis
Fractures
Cataracts

ABSTRACT

Giant cell arteritis and polymyalgia rheumatica are related inflammatory diseases affecting older individuals. Both are characterized by evidence of systemic inflammation, including elevations of acute phase reactants such as C-reactive protein and erythrocyte sedimentation rate. Polymyalgia rheumatica is a clinical syndrome characterized by symmetric pain and stiffness in the shoulder and thigh girdle, with prominent morning stiffness, and exquisite responsiveness to low-dose corticosteroid therapy. Giant cell arteritis is a large vessel vasculitis in which polymyalgic symptoms can be present in the majority of patients but characterized more specifically by large vessel inflammation that can result in ischemic complications, including headaches, jaw claudication, and most concerning, vision loss. Timely diagnosis of giant cell arteritis is essential, because vision loss, once incurred, is generally irreversible, whereas therapy with corticosteroids is protective against that dreaded complication, and typically affords prompt resolution of symptoms. The diagnosis of giant cell arteritis is generally supported by temporal artery biopsy, but large vessel imaging, including ultrasound, MRI/MRA, and PET scanning are emerging as useful diagnostic modalities. Therapy of both disorders is primarily with corticosteroids, which are effective in low doses in polymyalgia rheumatica, and in modest to high doses in giant cell arteritis. The morbidity of corticosteroids particularly with prolonged use in this vulnerable population is substantial. In patients with giant cell arteritis, the addition of tocilizumab, which is an anti-interleukin 6 receptor antibody, can improve response rates and allow for a more rapid tapering of the corticosteroid dose.

muscle ischemia on chewing occur in 50% of patients. Lingual and maxillary artery involvement can lead to jaw or tongue pain on chewing or talking. A dry, nonproductive cough can be a feature of the disease and often may direct the clinician away from considering giant cell arteritis and more toward consideration of an infectious or neoplastic respiratory cause of the symptoms. Rarely, mononeuritis multiplex or sensorineural hearing loss can occur but should lead the clinician to consider other possible vasculitides such as antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis or polyarteritis nodosa.

Fixed or intermittent symptoms related to vasculitic involvement of the ophthalmic arteries and its branches are the most dreaded in this illness and demand immediate therapeutic intervention.[3] These symptoms are related to vascular narrowing due to both active inflammation and endothelial injury–mediated vasospasm. Decreased vision secondary to arteritis is the most common serious consequence of giant cell arteritis, occurring in 20 to 50% of patients who present to ophthalmologists. It is the presenting symptom in 60% of patients with giant cell arteritis who develop visual loss. A careful history of most patients who present with "sudden" visual loss reveals that preceding headache, constitutional symptoms, and polymyalgia rheumatica occurred in approximately 40% of patients. Even the evolution of the visual loss is often staggered, with amaurosis fugax in 10% and a partial field defect progressing to complete blindness over days. If giant cell arteritis remains untreated, the second eye may become involved within 1 to 2 weeks.

Five percent of patients with giant cell arteritis may present with diplopia or ptosis, which may precede visual loss. The final visual abnormality can be a composite of many ischemic events occurring together in the optic nerve, the extraocular muscles, the chiasm, and the brain itself.

Large artery involvement most commonly presents as arm or leg claudication; rarer manifestations are stroke,[4] subclavian steal syndrome, intestinal infarction, and symptomatic aortic aneurysm. Some older patients classified as having giant cell arteritis can present with large vessel disease resembling Takayasu arteritis (Chapters 63) clinically, with a paucity of cranial ischemic symptoms but often the presence of polymyalgia-like symptoms. Conversely, in patients presenting with typical giant cell arteritis with cranial symptoms and a positive temporal artery biopsy, large vessel disease with aortic wall thickening is markedly more frequent even early in the disease course.

Steroid-treated polymyalgia rheumatica and giant cell arteritis are self-limited illnesses that clinically persist for 1 to 2 years in most patients. However, a subgroup of patients with both disorders can have active inflammatory disease as manifested by persistent symptoms and blood test signs of active inflammation for 7 to 10 years.

The major feared outcome in giant cell arteritis is ischemic complications of the disease, most often vision loss or, less frequently, cerebrovascular accident. Vision loss is uncommon after glucocorticoid therapy is instituted, but it can occur early in the course of treatment and is usually irreversible.

Thoracic aneurysms with giant cells in the tissue can develop as long as 15 years after the diagnosis, successful treatment, and discontinuation of steroids. Indeed, the incidence of thoracic and aortic aneurysms is markedly higher in patients with a prior history of presumably successfully treated giant cell arteritis than in age-matched control subjects. Giant cell arteritis is also associated with increased risks for myocardial infarction, stroke, and peripheral vascular disease.

DIAGNOSIS

The diagnoses of polymyalgia rheumatica and giant cell arteritis are based on clinical findings, with supporting but not diagnostic aid obtained from laboratory tests and temporal artery biopsy (Fig. 250-1).[5,6] However, both polymyalgia rheumatica and giant cell arteritis should always be considered in the setting of a fever of unknown origin (Chapter 259) because symptoms and signs can be occult or the history incomplete.

The laboratory hallmark of polymyalgia rheumatica and giant cell arteritis is an elevation in acute phase reactants such as the ESR and C-reactive protein. The ESR is usually in excess of 50 mm/hour and may exceed 100 mm/hour. An ESR in the low 20s or 30s, however, does not exclude either diagnosis if other characteristic clinical features are present and especially if the patient is already taking corticosteroids.

Normocytic, normochromic anemia and thrombocytosis occur in approximately 50% of patients with both disorders and are excellent guides to the state of inflammation. The frequencies of rheumatoid factor, antinuclear antibody, ANCA, monoclonal proteins, and cryoglobulins are not higher than in age-matched control subjects, and complement is not reduced. Alkaline phosphatase activity may be elevated in one third of patients, primarily patients

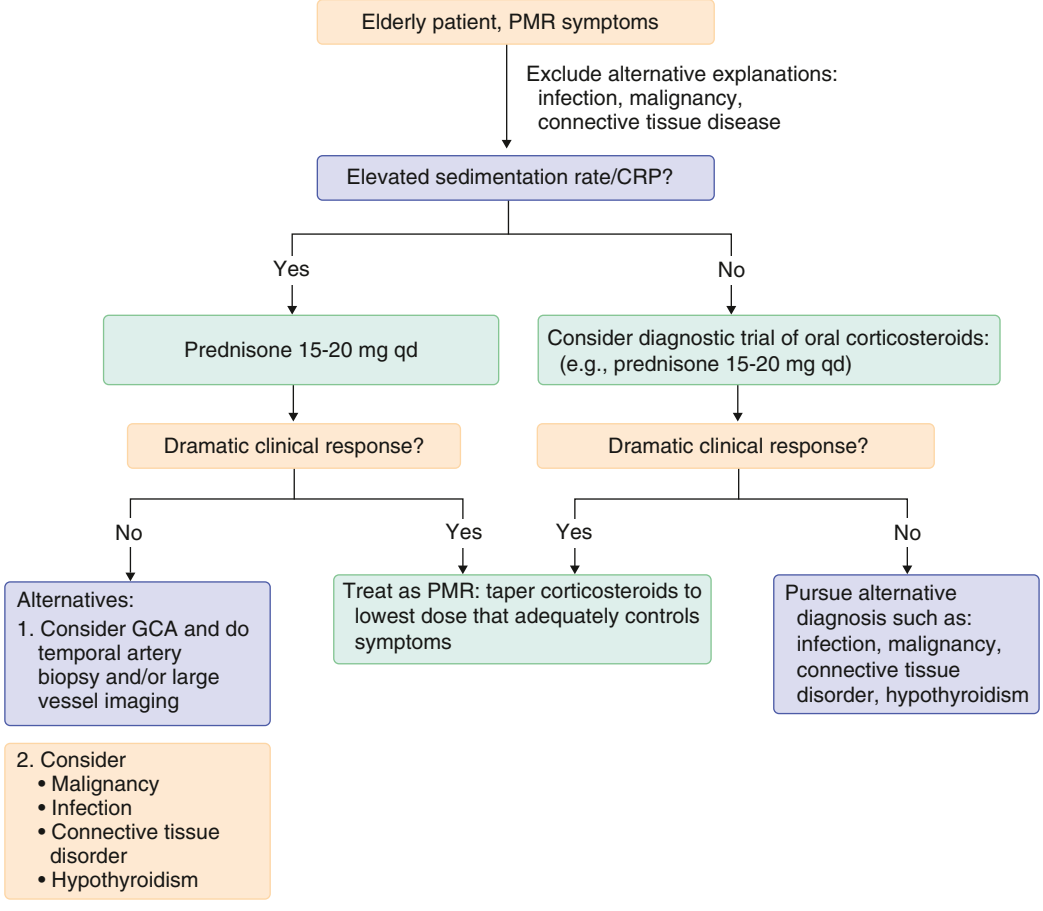

FIGURE 250-1. **Diagnostic algorithm for polymyalgia rheumatica (PMR).** CRP = C-reactive protein; GCA = giant cell arteritis; qd = once daily.

with giant cell arteritis. Creatine kinase levels are normal, and muscle biopsy is not indicated.

On ophthalmologic examination of patients with giant cell arteritis, the posterior ciliary arteries are the most frequently involved, so anterior ischemic optic neuropathy is the most common lesion and can easily be defined by an ophthalmologist. Occlusion of the central retinal artery and its branches is uncommon, so exudates, hemorrhages, and frank vasculitis are infrequent. A normal ophthalmologic examination should not dissuade the clinician from pursuing the diagnosis further.

Assessment of the Superficial Temporal Artery

Temporal artery tenderness, nodularity, and diminished pulsation are typical findings on physical examination in a patient with giant cell arteritis. On color duplex ultrasonography, a hypoechoic halo around the superficial temporal artery can be seen, but the sensitivity and specificity of this finding have varied among studies, and its incremental value above the physical examination is uncertain.[7,8] Stenosis or occlusion of temporal arteries on Doppler ultrasound is modestly sensitive and specific for the diagnosis of giant cell arteritis but is highly operator dependent. [18 F]Fluorodeoxyglucose-positron emission tomography (PET) may be helpful in identifying large vessel inflammation suggestive of giant cell arteritis, but it is not helpful in assessing the temporal arteries themselves, given their relatively small size and high background uptake in that area. Some studies suggest that MRI/magnetic resonance angiography (MRA) may be a helpful noninvasive diagnostic modality.[9] Superficial cranial arteries can be visualized, and mural inflammatory changes and luminal narrowing can be identified. Large vessel involvement also can be assessed. Conventional angiography is rarely used.

Temporal artery biopsy remains the diagnostic "gold standard" in giant cell arteritis. Given the relatively easy accessibility of the artery and potentially significant morbidity of therapy, histologic confirmation is usually recommended on the symptomatic side of the head, preferably including inflamed areas with tenderness or nodularity and incorporating 2 to 3 cm of vessel. Multiple sections should be requested because of the segmental nature of the disease process. Some rheumatologists routinely request bilateral biopsies, which may increase the likelihood of obtaining an abnormal finding by up to 5%, whereas others perform a contralateral biopsy if the first specimen is normal. Because of the skipped nature of the pathologic inflammatory lesions in the vessel wall, however as many as 20 to 30% of biopsy specimens may be normal despite an overwhelming diagnostic likelihood of giant cell arteritis. In most patients, however, diagnostic biopsy findings continue to be present for as long as 2 to 4 weeks after the clinical diagnosis is made and steroid treatment instituted, and may be seen even months into treatment.

Patients with pure polymyalgia rheumatica and no signs or symptoms of giant cell arteritis do not need a biopsy. However, because 10% of these patients may develop such clinical manifestations of giant cell arteritis within the next year, they should be told to report such symptoms immediately and have an urgent clinical assessment and possibly biopsy should those symptoms emerge.

Differential Diagnosis

The systemic nature of these disorders and the fact that they occur in elderly people demand careful diagnostic scrutiny to avoid missing a malignant neoplasm or major infection and possibly treating patients inappropriately with high-dose steroids.[10] This caveat is true in polymyalgia rheumatica because there is no definitive diagnostic test and in giant cell arteritis because biopsy findings may be normal despite active, vision-threatening vasculitis. Infections that must be considered if clinically appropriate include tuberculosis (Chapter 299), endocarditis (Chapter 61), and hepatitis B and C (Chapters 134 and 135). Malignant neoplasms such as lymphoma (Chapters 171 and 172) and multiple myeloma (Chapter 173) may mimic polymyalgia rheumatica, and an age-appropriate cancer evaluation is always indicated. Autoimmune disorders such as elderly-onset rheumatoid arthritis (Chapter 243), systemic lupus erythematosus (Chapter 245), dermatomyositis (Chapter 248), and other types of vasculitis (Chapter 249), must be considered in the differential diagnosis[11] and evaluated with serologic testing if suspected.

A form of elderly onset rheumatoid arthritis (Chapter 243) may mimic polymyalgia rheumatica because it presents with negative rheumatoid factor, a more proximal focus of joint inflammation, and a good response to low-dose prednisone. The distinction may be semantic because neither disorder tends to evolve into an erosive arthritis. A more protracted clinical course, however, is often seen in patients in whom distal synovitis is a prominent feature, and such patients are classified as having elderly onset rheumatoid arthritis.

TREATMENT

Both polymyalgia rheumatica and giant cell arteritis are highly responsive to corticosteroids, which are the treatment of choice.[12,13] Because of the high risk of visual loss, treatment should be started immediately when the clinical suspicion of giant cell arteritis is high even while awaiting temporary artery biopsy or its results. No physician should await an abnormal finding on temporal artery biopsy before making the presumptive diagnosis of giant cell arteritis in the setting of a characteristic clinical picture. If the biopsy is negative and an alternative diagnosis is likely, the corticosteroid can then be discontinued. For pure polymyalgia rheumatica, treatment is also based on the clinical diagnosis but is less urgent.

Whereas polymyalgia rheumatica usually responds to 15 mg of prednisone daily, giant cell arteritis usually requires 40 to 60 mg of prednisone per day in divided doses or higher doses if organ or tissue damage is present or threatened.[14] If visual symptoms are present as a fixed loss or amaurosis fugax in giant cell arteritis, the patient often should be treated with high-dose intravenous methylprednisolone with doses ranging from 40 mg every 8 hours to 1 g/day for up to 3 days, followed by high-dose oral steroids in divided doses. Within 2 to 3 days after the institution of steroids, most symptoms of polymyalgia rheumatica or giant cell arteritis clear rapidly, and patients describe a miraculous improvement, which supports the diagnosis. Conversely, a lack of rapid and significant improvement in signs, symptoms, and function within 5 to 7 days should lead the clinician to doubt the initial impression and consider an alternative diagnosis (e.g., tumor or infection), although some patients with giant cell arteritis might require a higher steroid dose.

The steroid dose is then maintained for 2 to 3 weeks, during which the ESR, C-reactive protein, hemoglobin, and platelet counts normalize. A steroid taper is then instituted and guided by the symptomatic response. In polymyalgia rheumatica, taper is commonly by 1 mg every 7 to 10 days; in giant cell arteritis, taper is by 5 to 10 mg every 7 to 10 days. In giant cell arteritis, alternate-day corticosteroid regimens are not recommended because of higher rates of treatment failure.

Treatment should not be based primarily in the decline in the ESR because an elderly patient would be subjected inappropriately to a dangerously high cumulative dose of steroids with their attendant side effects. An increased dose of prednisone should be based on a change in symptoms, not solely on an increase in the ESR. One possible exception is in a patient with a history of giant cell arteritis and prior abrupt vision loss in one eye, in whom any further compromise of vision would be catastrophic. The effective dose for a flare often can be as low as 5 to 10 mg/day of prednisone and uncommonly up to 60 mg/day to control symptoms (e.g., visual abnormalities).

In giant cell arteritis,[A1,A2] adding tocilizumab (a humanized monoclonal anti-IL-6 receptor antibody at 162 mg subcutaneously weekly) to corticosteroid therapy results in higher remission rates, less cumulative glucocorticoid use, and higher likelihood of sustained remission at 12 months.[A3] With the use of tocilizumab, glucocorticoids can be tapered relatively rapidly (tapered to off by month 6) without complications. Tocilizumab may provide a significant steroid-sparing benefit in polymyalgia rheumatica as well,[A4,A5] but this drug is not FDA-approved for its treatment.

Antiplatelet or anticoagulant therapy has had a marginal benefit when used together with corticosteroids in patients with established giant cell arteritis in uncontrolled studies. As a result, adjunctive therapy with low-dose aspirin (e.g., 81 to 100 mg daily) should be considered for patients who have giant cell arteritis unless there is a contraindication to its use.

The goal is to attain the best disease control with the lowest dose of steroids. In most patients, prednisone can be tapered safely in 1 to 2 years. However, some patients may need to take low doses of steroids for 2 years or more. The higher the initial dose and cumulative dose, the greater the likelihood that the patient will develop a major steroid side effect such as sepsis, osteoporosis, osteonecrosis, diabetes, emotional lability, or myopathy (Chapter 28). Appropriate immunizations, osteoporosis regimens (calcium, vitamin D, and bisphosphonates), and metabolic monitoring are mandatory in all patients prescribed chronic steroid therapy.

Alternative immunosuppressive agents have been tested in both polymyalgia rheumatica and giant cell arteritis. In giant cell arteritis, methotrexate has yielded mixed results, is of uncertain benefit, and is not routinely incorporated as first-line therapy. In polymyalgia rheumatica, methotrexate may have a steroid-sparing effect and may reduce the number of flares, but the magnitude of benefit appears to be modest at best. At present, methotrexate is not routinely used. In individual patients with refractory disease or excessive morbidity from corticosteroids, however, the addition of weekly rheumatoid arthritis–level doses of methotrexate (7.5 to 20 mg/week) or azathioprine (2 mg/kg/day) may be helpful for selected patients under expert guidance. Cyclophosphamide also may be of value in patients with refractory disease and/or unacceptable corticosteroid toxicity, but adverse events are common, and this drug is rarely used even by experts.

Treatment with abatacept, a costimulatory molecule blocker, has shown modest benefit in terms of relapse-free survival at 12 months[A6] and is presently being evaluated in a larger trial.

PROGNOSIS

In most studies, survival rates for patients with polymyalgia rheumatica and giant cell arteritis are similar to those of unaffected persons of the same age.

251 INFECTIONS OF BURSAE, JOINTS, AND BONES

DOUGLAS R. OSMON

INFECTION OF BURSAE

Septic Bursitis

DEFINITION

Bursae are the satellite structures that form to protect tissues from bony prominences. The superficial bursae, including the olecranon, prepatellar, infrapatellar, and bursae over the first metatarsophalangeal bunions, are more likely to become infected than are the deep bursae, such as the subacromial, trochanteric, and iliopsoas bursae.

EPIDEMIOLOGY

Olecranon bursitis may occur in as many as 10 in 100,000 persons per year. The majority of cases occur in men, and antecedent trauma to the skin is frequent.

PATHOBIOLOGY

Septic bursitis of superficial bursae is most commonly due to direct inoculation through the overlying skin; less commonly, it is secondary to overlying cellulitis. Most cases of deep septic bursitis are due to contiguous spread from adjacent infected joints or hematogenous seeding.

Predisposing risk factors for septic bursitis include trauma to the skin. For example, olecranon septic bursitis may occur in plumbers, athletes, and patients with chronic obstructive pulmonary disease (COPD) who frequently lean on their elbows; prepatellar or infrapatellar septic bursitis can occur in housecleaners, gardeners, and carpet layers. At least one third of patients with septic bursitis have an underlying comorbid illness such as diabetes mellitus, rheumatoid arthritis, gout, COPD, or alcohol use disorder.

CLINICAL MANIFESTATIONS

In immunocompetent patients, septic bursitis often but not always presents with fever as well as erythema and warmth of the overlying skin; there may be swelling of the bursae. In contrast to patients with septic arthritis, patients with septic bursitis of superficial bursae have intact range of motion of the joints, which may be limited only at the extremes of flexion. Pain on motion of the joint and restriction of joint range of motion are highly suggestive of septic arthritis. Acute phase reactants such as C-reactive protein, the sedimentation rate, and the white blood cell (WBC) count may be elevated.

DIAGNOSIS

Radiography should be performed to look for a foreign body and to evaluate the surrounding bones. Aspiration of bursal fluid is helpful in the diagnosis of patients who have pain, erythema, and/or swelling of an affected area. However, given the risk for contaminating the bursa if the aspiration occurs through cellulitic skin, many clinicians choose to aspirate a bursa only if empirical antimicrobial therapy has failed. Ultrasound or computed tomography (CT) guidance greatly enhances the successful aspiration of superficial bursae. Care must be taken not to violate the joint space when aspirating a bursa to avoid inoculating it.

The leukocyte count of the bursal fluid is generally lower than what is seen in septic arthritis. A leukocyte count greater than 2000/μL has a sensitivity of 94% and a specificity of 79% for superficial (olecranon or prepatellar) bursitis. Bacterial culture and in vitro susceptibilities must be obtained; if additional fluid is available, a Gram stain may be obtained, although its sensitivity may be as low as 15%. The presence of crystals does not exclude the possibility of septic bursitis (Chapter 252). Concomitant bacteremia can occur, and blood cultures should be obtained before the initiation of therapy if possible.

Staphylococcus aureus (Chapter 267), which is the most common cause of septic bursitis, accounts for more than 70% of culture-proven cases,[1] followed by β-hemolytic streptococci. Aerobic gram-negative bacilli, including *Escherichia coli,* and pseudomonas, are less common causes of septic bursitis. Polymicrobial infection can also occur. Chronic bursitis may be associated with infections due to *Brucella* spp, atypical mycobacteria, or *Mycobacterium tuberculosis,* as well as fungi; the presence of these infections should raise the possibility of systemic infection.

Differential Diagnosis

In the immunocompetent host, nonseptic bursitis (Chapter 242) may have a somewhat more indolent presentation than septic bursitis. The differential diagnosis includes gout and pseudogout (Chapter 252), arthritis, and trauma with hemobursa. An overlying cellulitis may be confused with bursitis. Fever is usually not present in nonseptic bursitis because of mechanical or friction trauma.

TREATMENT

Treatment of septic bursitis is guided by knowledge of the putative underlying organisms, in most cases, *S. aureus* (Chapter 267). Because the Gram stain result is frequently negative and culture results are delayed, empirical therapy is guided by the clinical presentation, the host's risk factors, and knowledge of common pathogens causing infection. Most patients can be treated as outpatients,[2] but patients who are immunocompromised may require hospitalization for intravenous antibiotic therapy (Table 251-2).

Initial ambulatory treatment in patients without comorbid conditions may consist of an oral antistaphylococcal penicillin (e.g., dicloxacillin 500 mg orally four times daily) or a first-generation cephalosporin (e.g., cephalexin 500 mg orally four times daily). If community-acquired methicillin-resistant *S. aureus* (MRSA) is suspected, cotrimoxazole (e.g., one double-strength tablet orally twice daily), doxycycline (e.g., 100 mg orally twice daily), or minocycline may be added to one of these agents. In patients who are allergic to penicillin, oral clindamycin (e.g., 300 mg orally four times daily) or linezolid (e.g., 600 mg orally twice daily) may be used. In all cases, the choice among antibiotics and their doses should be guided by the patient's renal and hepatic function as well as any drug allergies or intolerances.

Patients who have severe inflammation, are septic, or are immunocompromised may require hospitalization for initiation of treatment with intravenous nafcillin, oxacillin, or cefazolin (see Table 251-2). If MRSA is suspected, intravenous vancomycin, daptomycin, or linezolid (see Table 251-2) should be used (Chapter 267). Vancomycin also can be used in patients who are allergic to penicillin.

The duration of antimicrobial therapy is guided by the clinical response and comorbid conditions. Antibiotics should be continued until bursal inflammation resolves. Resolution may require several weeks of intravenous or oral therapy and multiple aspirations. Failure of the septic bursitis to respond to initial antibiotic therapy mandates a second course of therapy. Recurrence thereafter or inability to drain the bursa adequately with needle aspiration is an indication for surgical intervention.

PREVENTION

Because superficial septic bursitis is often associated with occasional or avocational activities involving kneeling or resting on the elbows, using protective padding may be helpful.

PROGNOSIS

The optimal duration of therapy is unknown, but prognosis of superficial bursitis is generally excellent. The presence of comorbid conditions, especially conditions associated with deep bursal infections (e.g., including septic arthritis, bacteremia, and osteomyelitis), is associated with more intractable and difficult disease.

INFECTION OF JOINTS

Septic Arthritis

DEFINITION

Septic arthritis, which refers to infection of a joint by a microorganism, is associated with increased morbidity and mortality as well as loss of articular

251 INFECTIONS OF BURSAE, JOINTS, AND BONES

DOUGLAS R. OSMON

INFECTION OF BURSAE

Septic Bursitis

DEFINITION

Bursae are the satellite structures that form to protect tissues from bony prominences. The superficial bursae, including the olecranon, prepatellar, infrapatellar, and bursae over the first metatarsophalangeal bunions, are more likely to become infected than are the deep bursae, such as the subacromial, trochanteric, and iliopsoas bursae.

EPIDEMIOLOGY

Olecranon bursitis may occur in as many as 10 in 100,000 persons per year. The majority of cases occur in men, and antecedent trauma to the skin is frequent.

PATHOBIOLOGY

Septic bursitis of superficial bursae is most commonly due to direct inoculation through the overlying skin; less commonly, it is secondary to overlying cellulitis. Most cases of deep septic bursitis are due to contiguous spread from adjacent infected joints or hematogenous seeding.

Predisposing risk factors for septic bursitis include trauma to the skin. For example, olecranon septic bursitis may occur in plumbers, athletes, and patients with chronic obstructive pulmonary disease (COPD) who frequently lean on their elbows; prepatellar or infrapatellar septic bursitis can occur in housecleaners, gardeners, and carpet layers. At least one third of patients with septic bursitis have an underlying comorbid illness such as diabetes mellitus, rheumatoid arthritis, gout, COPD, or alcohol use disorder.

CLINICAL MANIFESTATIONS

In immunocompetent patients, septic bursitis often but not always presents with fever as well as erythema and warmth of the overlying skin; there may be swelling of the bursae. In contrast to patients with septic arthritis, patients with septic bursitis of superficial bursae have intact range of motion of the joints, which may be limited only at the extremes of flexion. Pain on motion of the joint and restriction of joint range of motion are highly suggestive of septic arthritis. Acute phase reactants such as C-reactive protein, the sedimentation rate, and the white blood cell (WBC) count may be elevated.

DIAGNOSIS

Radiography should be performed to look for a foreign body and to evaluate the surrounding bones. Aspiration of bursal fluid is helpful in the diagnosis of patients who have pain, erythema, and/or swelling of an affected area. However, given the risk for contaminating the bursa if the aspiration occurs through cellulitic skin, many clinicians choose to aspirate a bursa only if empirical antimicrobial therapy has failed. Ultrasound or computed tomography (CT) guidance greatly enhances the successful aspiration of superficial bursae. Care must be taken not to violate the joint space when aspirating a bursa to avoid inoculating it.

The leukocyte count of the bursal fluid is generally lower than what is seen in septic arthritis. A leukocyte count greater than 2000/μL has a sensitivity of 94% and a specificity of 79% for superficial (olecranon or prepatellar) bursitis. Bacterial culture and in vitro susceptibilities must be obtained; if additional fluid is available, a Gram stain may be obtained, although its sensitivity may be as low as 15%. The presence of crystals does not exclude the possibility of septic bursitis (Chapter 252). Concomitant bacteremia can occur, and blood cultures should be obtained before the initiation of therapy if possible.

Staphylococcus aureus (Chapter 267), which is the most common cause of septic bursitis, accounts for more than 70% of culture-proven cases,[1] followed by β-hemolytic streptococci. Aerobic gram-negative bacilli, including *Escherichia coli,* and pseudomonas, are less common causes of septic bursitis. Polymicrobial infection can also occur. Chronic bursitis may be associated with infections due to *Brucella* spp, atypical mycobacteria, or *Mycobacterium tuberculosis,* as well as fungi; the presence of these infections should raise the possibility of systemic infection.

Differential Diagnosis

In the immunocompetent host, nonseptic bursitis (Chapter 242) may have a somewhat more indolent presentation than septic bursitis. The differential diagnosis includes gout and pseudogout (Chapter 252), arthritis, and trauma with hemobursa. An overlying cellulitis may be confused with bursitis. Fever is usually not present in nonseptic bursitis because of mechanical or friction trauma.

TREATMENT

Treatment of septic bursitis is guided by knowledge of the putative underlying organisms, in most cases, *S. aureus* (Chapter 267). Because the Gram stain result is frequently negative and culture results are delayed, empirical therapy is guided by the clinical presentation, the host's risk factors, and knowledge of common pathogens causing infection. Most patients can be treated as outpatients,[2] but patients who are immunocompromised may require hospitalization for intravenous antibiotic therapy (Table 251-2).

Initial ambulatory treatment in patients without comorbid conditions may consist of an oral antistaphylococcal penicillin (e.g., dicloxacillin 500 mg orally four times daily) or a first-generation cephalosporin (e.g., cephalexin 500 mg orally four times daily). If community-acquired methicillin-resistant *S. aureus* (MRSA) is suspected, cotrimoxazole (e.g., one double-strength tablet orally twice daily), doxycycline (e.g., 100 mg orally twice daily), or minocycline may be added to one of these agents. In patients who are allergic to penicillin, oral clindamycin (e.g., 300 mg orally four times daily) or linezolid (e.g., 600 mg orally twice daily) may be used. In all cases, the choice among antibiotics and their doses should be guided by the patient's renal and hepatic function as well as any drug allergies or intolerances.

Patients who have severe inflammation, are septic, or are immunocompromised may require hospitalization for initiation of treatment with intravenous nafcillin, oxacillin, or cefazolin (see Table 251-2). If MRSA is suspected, intravenous vancomycin, daptomycin, or linezolid (see Table 251-2) should be used (Chapter 267). Vancomycin also can be used in patients who are allergic to penicillin.

The duration of antimicrobial therapy is guided by the clinical response and comorbid conditions. Antibiotics should be continued until bursal inflammation resolves. Resolution may require several weeks of intravenous or oral therapy and multiple aspirations. Failure of the septic bursitis to respond to initial antibiotic therapy mandates a second course of therapy. Recurrence thereafter or inability to drain the bursa adequately with needle aspiration is an indication for surgical intervention.

PREVENTION

Because superficial septic bursitis is often associated with occasional or avocational activities involving kneeling or resting on the elbows, using protective padding may be helpful.

PROGNOSIS

The optimal duration of therapy is unknown, but prognosis of superficial bursitis is generally excellent. The presence of comorbid conditions, especially conditions associated with deep bursal infections (e.g., including septic arthritis, bacteremia, and osteomyelitis), is associated with more intractable and difficult disease.

INFECTION OF JOINTS

Septic Arthritis

DEFINITION

Septic arthritis, which refers to infection of a joint by a microorganism, is associated with increased morbidity and mortality as well as loss of articular

ABSTRACT

Septic bursitis, arthritis, and osteomyelitis most commonly result from direct inoculation through the skin, by hematologic spread, or following bone and joint surgery. Predisposing factors include immunosuppression, autoimmune diseases, diabetes mellitus, alcohol use disorder, and antecedent surgery, including bowel and bladder procedures and joint arthroplasty. Diagnosis is based on clinical suspicion, abnormal laboratory tests (e.g., elevated sedimentation rate, C-reactive protein, and white blood cell count), and identification of causative organisms by serology and/or in joint or bursal fluid, blood, or biopsy of bone or synovial tissue. Magnetic resonance imaging, computed tomography, radiography, and nuclear medicine techniques may aid in identification of foci of infection. Initial treatment of suspected infection is empirical, guided by the clinical presentation and informed by identification of the causative organism(s). Surgical treatment includes débridement of the affected musculoskeletal structure. Management of prosthetic joint infections requires débridement with either initial retention of the prosthesis, resection arthroplasty, or rarely amputation. Successful management is dependent on the effectiveness of the medical and surgical therapies, the maintenance of adequate vascularization for the affected tissues, and the ability to manage comorbid conditions.

integrity and function. Septic arthritis is usually caused by a bacterial infection, but other microorganisms also can cause infections with clinical characteristics that differ from those of bacterial infections.

NONGONOCOCCAL SEPTIC ARTHRITIS

EPIDEMIOLOGY

The incidence of septic arthritis affecting native joints is approximately 10 per 100,000 patient years. Among patients presenting with an acutely swollen and painful joint, bacterial pathogens are the most common etiology. Nongonococcal septic arthritis is the most common form of septic arthritis and is somewhat more common in men than in women.

PATHOBIOLOGY

Staphylococci or streptococci are the most common pathogen to cause septic arthritis, but the microbiology depends on the mechanism of the infection (Table 251-1). Septic arthritis can result from direct inoculation (e.g., accidents, bites, surgery) or by extension from infected bone into an adjacent joint space. Approximately 75% of cases are due to hematogenous spread, particularly in patients who use injection drugs, have indwelling catheters, or are immunocompromised. Iatrogenic septic arthritis due to needle arthrocentesis (is estimated to be between <1/10,000 to 1/3000 procedures) or arthroscopy (estimated to be between 0.0009 to 1.1%) is very rare.

Bacteria causing septic arthritis produce an acute inflammatory reaction in the synovial membrane. Synovial hyperplasia and inflammatory cell immigration, with the release of pro-inflammatory and cartilage-destroying cytokines and proteases, result in damage to cartilage and bone. Bacterial toxins and DNA as well as superantigens, such as those seen in staphylococcal toxic shock syndrome, also damage cartilage and bone.

Risk factors for the development of septic arthritis include penetrating trauma, diabetes, alcohol use disorder, cutaneous ulcers, injection drug use, prosthetic joints, rheumatoid arthritis, osteoarthritis, and low socioeconomic status, as well as advanced age, skin infection, indwelling intravenous catheters, cancer, and immunosuppressive therapies, including biologic response modifiers used in the management of autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease.

CLINICAL MANIFESTATIONS

Most patients with bacterial arthritis feel ill and have fever. Immuno-compromised and elderly patients may not have a marked febrile response. Most cases (>80%) of septic arthritis are monoarticular; the knee is involved in more than 50% of cases. Polyarticular joint sepsis may be seen in immunocompromised patients and patients with rheumatoid arthritis (Chapter 243) or systemic lupus erythematosus (Chapter 245). Such patients frequently lack typical signs and symptoms of infection and may not appear to be particularly ill at presentation,[3] but they may have rapid cardiovascular decompensation, particularly if they are taking glucocorticosteroids, other immunosuppressive agents, or biologic response modifiers, including tumor necrosis factor-α (TNF-α) inhibitors.

Patients with septic arthritis affecting nondiarthrodial joints, such as the acromioclavicular or sacroiliac joints, may have a history of injection drug use or may have intravenous catheters in place to treat other medical conditions. Infection of the symphysis pubis is associated with previous urinary tract or gynecologic surgery, pelvic malignancy, injection drug use, or vigorous weight-bearing physical activity, such as long-distance running, in female athletes.

DIAGNOSIS

The diagnosis of septic arthritis is challenging because its signs and symptoms overlap those of other nonseptic inflammatory joint diseases (e.g., osteoarthritis [Chapter 241], gout [Chapter 252], and rheumatoid arthritis [Chapter 243]) that themselves can increase the risk for septic arthritis (Fig. 251-1).[4,5] Ultrasonography can confirm the presence of fluid. Plain radiography should be performed to evaluate the surrounding bones and joint space and to provide a baseline for comparison after therapy is completed. Imaging modalities such as plain radiography, magnetic resonance imaging (MRI), and CT are useful in cases of diagnostic uncertainty and to assess for possible associated osteomyelitis. Blood cultures are often positive.

If septic arthritis is suspected, synovial fluid arthrocentesis is indicated, and the fluid should be examined for bacterial culture and Gram stain, although the latter is positive in fewer than 50% of patients.[6] Specific cultures and stains for fungal and mycobacterial organisms should obtained in patients who have a history of exposure or if prior antibacterial therapy has failed. Polymerase chain reaction (PCR) assays and a serum Lyme serology are useful tools for diagnosing less common joint infections such as *Borrelia* in patients with risk factors for Lyme disease (Chapter 296).

Other helpful examinations include leukocyte count and differential, as well as evaluation of the synovial fluid for the presence of crystals (Chapter 252). The total WBC count and differential in synovial fluid is helpful in distinguishing infected from noninfected joints in immunocompetent patients. The higher the synovial fluid leukocyte count and percent neutrophils the more likely it is that

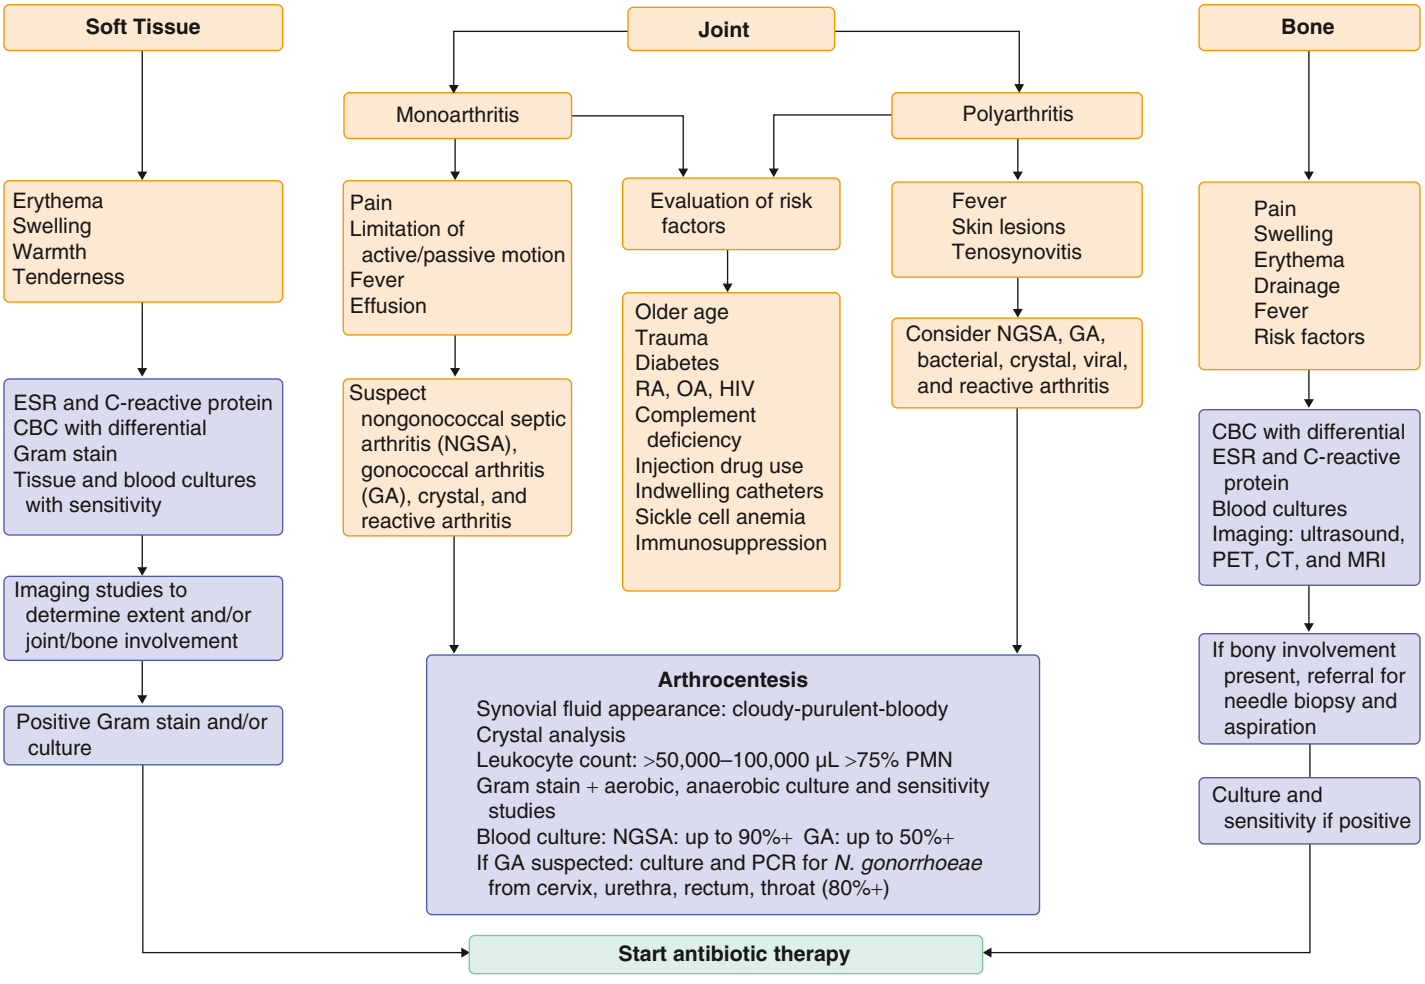

FIGURE 251-1. Clinical evaluation of infections of soft tissues, joints, and bone. CBC = complete blood count; CT = computed tomography; ESR = erythrocyte sedimentation rate; GA = gonococcal arthritis; HIV = human immunodeficiency virus; IV = intravenous; MRI = magnetic resonance imaging; NGSA = nongonococcal septic arthritis; OA = osteoarthritis; PCR = polymerase chain reaction; PET = positron emission tomography; PMN = polymorphonuclear leukocyte; RA = rheumatoid arthritis.

the septic arthritis is due to bacterial pathogens, with or without concomitant crystalline disease. It is important to realize, however, that a WBC count less than 50,000/µL, especially in immunocompromised patients, can be associated with septic arthritis, so the absolute WBC count in synovial fluid is not, by itself, a reliable way to confirm or exclude a diagnosis of septic arthritis. The presence of gout or pseudogout crystals does not exclude the possibility of septic arthritis, particularly in patients whose WBC count is above 50,000/µL. Preliminary data suggest that the level of presepsin in synovial fluid may help rapidly distinguish septic arthritis from crystal arthritis.[7]

A frequent clinical scenario is the patient who is receiving anticoagulation therapy. Because of the rapidly destructive nature of septic arthritis and the often profound systemic consequences, therapeutic anticoagulation typically is not a contraindication to arthrocentesis. The procedure may be assisted by ultrasound guidance, especially when only a small amount of joint fluid is present or when the joint is difficult to aspirate. Ultrasound or CT-guided arthrocentesis is particularly useful for aspiration of deep joints such as the hips and nondiarthrodial joints.

A finding of microorganisms in the joint should lead to an appropriate history and physical examination to identify a source of hematogenous infection, such as cellulitis, pneumonia, or urinary tract infection. Staphylococci and β-hemolytic streptococci may enter directly through open wounds, whereas gram-negative infection may be associated with bowel or bladder disease. Blood cultures are positive in up to 50% of patients with bacterial septic arthritis and should be obtained in all patients in whom this diagnosis is suspected.

Differential Diagnosis

Symptoms of septic arthritis, such as acute joint pain, swelling, and even fever, with an increase in acute phase reactants, can be caused by crystalline arthritis (Chapter 252), especially pseudogout and gout, as well as psoriatic arthritis (Chapter 244) and reactive arthritis (Chapter 244). In patients who have preexisting inflammatory joint disease, such as rheumatoid arthritis (Chapter 243), septic arthritis may be suspected if a patient has the sudden onset of acute or subacute monoarticular or pauciarticular joint swelling when the disease is otherwise well controlled. The presence or absence of fever is not a reliable indicator of an infected joint.

TREATMENT

As soon as the joint has been aspirated and ideally after blood cultures have been obtained, prompt antibiotic treatment must be instituted.[8] Removal of purulent material and, where appropriate, débridement are essential. The choice of empirical antimicrobial therapy is based on which organisms are thought to be the likely cause of the septic arthritis and on the results of Gram stain and culture (Table 251-2). No advantage of one antibiotic regimen over another has been demonstrated. If the initial Gram stain of the synovial fluid reveals gram-positive cocci, vancomycin is recommended, given the increasing frequency of infection due to MRSA and the need to initiate effective antimicrobial therapy as soon as possible. Daptomycin and linezolid are alternative agents. If the initial Gram stain reveals gram-negative bacilli, an agent with broad coverage, including activity against *Pseudomonas aeruginosa,* is recommended. Such agents include ceftazidime, cefepime, imipenem, meropenem, piperacillin-tazobactam, and ciprofloxacin. If the Gram stain result is negative, vancomycin alone in immunocompetent patients or in those unlikely to have gram-negative infection based on history and examination, or vancomycin plus one of the gram-negative antibacterials listed, is reasonable. When culture and in vitro susceptibility results are available, therapy can be modified. The duration of antibacterial therapy usually ranges from 2 to 6 weeks, with data suggesting that one aspiration and 2 weeks of therapy are usually adequate.[A1] The presence of bacteremia, osteomyelitis, or infective endocarditis will dictate a longer duration of therapy.

The role of arthroscopic versus needle versus open drainage of the joint remains unsettled.[9,10] Surgical management is appropriate for septic arthritis of the hip, for patients who fail to respond to serial needle aspiration and antibiotic therapy, and for patients who appear to be developing life-threatening complications such as necrotizing fasciitis. Patients should be mobilized as rapidly as possible to prevent joint contractures. The concomitant use of oral dexamethasone for 4 days can lead to more rapid symptomatic improvements in children,[A2] but no randomized trials have been reported in adults.

TABLE 251-2 ANTIMICROBIAL THERAPY FOR SELECTED MICROORGANISMS IN SEPTIC ARTHRITIS OR OSTEOMYELITIS IN ADULTS

MICROORGANISM	FIRST CHOICE*	ALTERNATIVE CHOICE
Methicillin/oxacillin/nafcillin–sensitive staphylococci	Nafcillin sodium or oxacillin sodium 1.5-2 g IV q4-6h for 4-6 wk *or* cefazolin 1-2 g IV q8h	Vancomycin 15 mg/kg IV q12h or daptomycin 6-10 mg/kg IV q24h for 4-6 wk; dalbavancin 1500 mg IV on days 1 and 8†
Methicillin/oxacillin/nafcillin-resistant staphylococci (MRSA)	Vancomycin‡ 15 mg/kg IV q12h *or* daptomycin 6-10 mg/kg IV q24h	Linezolid 600 mg PO/IV q12h *or* daptomycin 6-10 mg/kg IV q24h‡ *or* 500-750 mg PO/IV daily; dalbavancin 1500 mg IV on days 1 and 8†
Penicillin-sensitive streptococci	Aqueous penicillin G 20 × 10^6 U/24 hr IV either continuously or in six equally divided daily doses *or* ceftriaxone 2 g IV q24h *or* cefazolin 1-2 g IV q8h	Vancomycin 15 mg/kg IV q12h; dalbavancin 1500 mg IV on days 1 and 8
Enterococci Penicillin and vancomycin susceptible	Aqueous crystalline penicillin G 20 × 10^6 U/24 hr IV either continuously or in six equally divided daily doses *or* ampicillin sodium 12 g/24 hr IV either continuously or in six equally divided daily doses; the addition of gentamicin sulfate 1 mg/kg IV or IM q8h for 1-2 wk is *optional*	Vancomycin‡ 15 mg/kg IV q12h; the addition of gentamicin sulfate 1 mg/kg IV or IM q8h for 1-2 wk is *optional or* daptomycin 6-10 mg/kg IV q24h for 4-6 wk
Enterobacteriaceae (e.g., *Salmonella*)	Ceftriaxone 1-2 g IV q24h	Ciprofloxacin‡ 500-750 mg PO q12h
Pseudomonas aeruginosa	Cefepime 2 g IV q8-12h	Ciprofloxacin‡ 750 mg PO q12h *or* ceftazidime 2 g IV q8h or imipenem 500 mg IV q6h or meropenem

*Antimicrobial selection should be based on in vitro sensitivity data, as well as allergies, intolerances, and drug interactions in individual patients.

†See text for data for treatment of osteomyelitis.

‡Doses shown are based on normal renal and hepatic function and may need to be adjusted or serum levels monitored (vancomycin).

IV = intravenous; MRSA = methicillin-resistant *Staphylococcus aureus*; PO = oral.

PREVENTION

In patients requiring immunosuppression or glucocorticosteroid therapy to manage their underlying diseases, every effort should be made to use the lowest possible dose of these medications.

PROGNOSIS

About 40% of patients with septic arthritis have less than a complete recovery,[11] particularly older patients and patients with preexisting diseases of the joints such as osteoarthritis or rheumatoid arthritis. The outcome may be severe enough to warrant consideration of joint replacement.

Total joint replacement after septic arthritis carries about a 12% risk of infection. Patients with diabetes and drug-resistant organisms are at higher risk.[12]

S. aureus infection (Chapter 267) is associated with poor joint outcomes in more than 50% of patients, and mortality may be as high as 10 to 15%, particularly in patients who are immunocompromised or have polyarticular sepsis. A prior history of native joint arthritis increases the risk of prosthetic joint infection following joint replacement.

GONOCOCCAL SEPTIC ARTHRITIS

EPIDEMIOLOGY

Neisseria gonorrhoeae (Chapter 275) is a common cause of polyarthralgias and arthritis as well as oligoarticular arthritis and tenosynovitis in otherwise young, healthy patients. Disseminated gonococcal infection occurs in 0.5 to 3% of patients with gonorrhea (Chapter 275), and many of these patients develop arthritis. Most patients do not have a recent history of a symptomatic genital infection. Disseminated gonococcal infection and septic arthritis due to *N. gonorrhoeae* occur two to three times more often in women than in men. Predisposing factors for disseminated gonococcal infection with arthritis include pregnancy, recent menstruation, drug-induced or congenital complement deficiencies (C5, C6, C7, or C8; Chapter 37), and systemic lupus erythematosus (Chapter 245).

CLINICAL MANIFESTATIONS

Patients with gonococcal arthritis usually present with one of two clinical syndromes. The first is a purulent arthritis without skin lesions; the second is the triad of tenosynovitis, dermatitis, and polyarthralgias without purulent arthritis.[13] The latter patients may have bacteremia and fever, as well as maculopapular, vesicular, necrotic, pustular skin lesions anywhere on the integument (see Fig. 275-4). The arthritis is usually asymmetrical and may involve large or small joints, typically the elbows and knees or more distal joints.

DIAGNOSIS

A high degree of clinical suspicion is required for diagnosis because many patients are asymptomatic for the primary infection. A thorough joint evaluation is important, as is an evaluation of soft tissues, particularly for tenosynovitis affecting the hands and feet. Cultures of blood, endocervix, and urethra are essential; cultures of the pharynx and rectum may be very helpful. *N. gonorrhoeae* is isolated in less than 30% of patients with the tenosynovitis-dermatitis syndrome and in about 50% of patients with monoarthritis. PCR testing is recommended and can detect gonococcal DNA in synovial fluid, skin lesions, urine, throat, and rectal samples, even when cultures are negative. Cultures should be submitted on Thayer-Martin media. Patients with suspected gonococcal arthritis should be screened for other possible coexisting sexually transmitted infections (Chapter 264) such as syphilis (Chapter 295), human immunodeficiency virus (Chapter 355), and chlamydia (Chapter 294), as well as hepatitis B and C (Chapters 134 and 135).

TREATMENT

Ceftriaxone (e.g., 1 g intramuscularly or intravenously every 24 hours) is administered initially in nonallergic patients and continued until clinical improvement, at which time the patient can be switched to oral therapy depending on clinical assessment, comorbid conditions, and in vitro susceptibilities. Given emerging antimicrobial resistance, the most recent U.S. Centers for Disease Control and Prevention (CDC) guidelines for treating *N. gonorrhoeae* septic arthritis (www.cdc.gov/std/gonorrhea/treatment.htm) should be consulted and followed. Gonococcal effusions should be drained as is recommended for staphylococcal arthritis. Patients also should be treated for concomitant chlamydia (with doxycycline 100 mg twice daily for 7 days).

PROGNOSIS

Most patients respond well to outpatient therapy, with complete resolution of the infection.

VIRAL ARTHRITIS

Patients with viral syndromes may have polyarthralgias or inflammatory polyarthritis, which can mimic rheumatoid arthritis (Chapter 243). The most common viral infections associated with arthritis include hepatitis A, B, and C (Chapters 134 and 135); cytomegalovirus (Chapter 347); parvovirus B19 (Chapter 342); rubella (Chapter 339); measles (Chapter 338); and HIV (Chapter 359). Other forms of viral arthritis are caused by adenovirus (Chapter 333), echovirus (Chapter 349), Epstein-Barr virus (Chapter 348), and herpes zoster (Chapter 346) in North America and Europe; chikungunya and o'nyong-nyong viruses, especially in Africa (Chapter 352); and Ross River virus in Australia (Chapter 352). Arthritis related to viral infections is likely to be principally reactive in nature,[14] rather than being caused by direct synovial infection.

Chikungunya virus infection (chikungunya fever; Chapter 352) is an arthropod-borne arbovirus infection that over recent decades has dispersed from tropical and subtropical regions of Africa and Asia to affect millions of people worldwide as an emerging threat to global public health.[15] The illness occurs in two phases: an acute viremia followed by a chronic arthritis that can be accompanied by severe, incapacitating arthralgia. Attempts to isolate chikungunya virus from synovial fluid have been unsuccessful,[16] and the chronic arthritis is now thought to be a postinfectious autoinflammatory disorder rather than persistent viral infection. It shares many clinical features with rheumatoid arthritis and responds variably to different disease-modifying antirheumatic drugs.

OTHER FORMS OF INFECTIOUS ARTHRITIS

FUNGAL ARTHRITIS

Fungal arthritis is unusual and most commonly occurs in immunocompromised patients. Treatment with high doses of immunosuppressants, anti-TNF agents, and possibly other biologic response modifiers used for rheumatoid arthritis and other autoimmune diseases may increase the risk for fungal infections. The infections are often systemic and may be indolent. An understanding of the epidemiology of the organisms as well as the patient's risk factors, including occupational and avocational risk factors, is essential to the diagnosis. The most common fungi in the United States include *Blastomyces dermatitidis, Coccidioides immitis*, and *Histoplasma capsulatum* (Chapter 308). *Sporothrix schenckii* fungal infections may be seen especially in gardeners. More unusual infections occur in immunocompromised patients, including *Aspergillus* (Chapter 311), *Candida* (Chapter 310), and *Cryptococcus* (Chapter 309). The treatment of fungal infections is detailed in their respective chapters.

LYME ARTHRITIS

Lyme disease (Chapter 296) usually causes oligoarticular arthritis, most commonly affecting the knee. Antibiotic treatment (see Chapter 296) is effective. Polyarticular disease affecting the small joints has been associated with human leukocyte antigen (HLA)-DR4, which is found in greater frequency in patients with rheumatoid arthritis.

MYCOPLASMA AND UREAPLASMA ARTHRITIS

Mycoplasma hominis (Chapter 293) causes an oligoarticular or monoarticular arthritis. Risk factors for mycoplasma and ureaplasma arthritis include immunosuppression and congenital or drug-induced hypogammaglobulinemia. Mycoplasma septic arthritis also can occur after childbirth. Nucleic acid amplification tests are more sensitive than culture for the diagnosis of these infections. The treatment of choice is tetracyclines, usually doxycycline; alternatively, clindamycin or fluoroquinolones can be used (see Chapter 293).

TUBERCULOUS ARTHRITIS

Most cases of tuberculosis (Chapter 299) in Canada, the United States, Western Europe, Australia, and New Zealand occur in immigrants. The arthritis is usually monoarticular or oligoarticular and affects larger joints. Tuberculosis should be suspected in patients who have refractory monoarticular or pauciarticular arthritis thought to be secondary to another bacterial infection or to a systemic inflammatory disease such as rheumatoid arthritis. Screening for tuberculosis is mandatory for all patients before beginning treatment with immunosuppressive drugs or biologic response modifiers.

The diagnosis of tuberculosis may be delayed by a lack of clinical suspicion because patients may not have pulmonary disease. Atypical mycobacterial infection may occur in fishermen and immunocompromised patients. Clinical suspicion and culture of synovial fluid or synovial membrane obtained at biopsy are essential to the diagnosis.

TREATMENT

Appropriate treatment for septic arthritis due to tuberculosis is based on guidelines and in vitro susceptibility testing, but it often includes isoniazid, ethambutol, or rifampin and pyrazinamide as empirical therapy (see Table 299-4). Atypical mycobacteria are often not susceptible to traditional antituberculous agents, and infectious disease consultation is recommended.

SYPHILIS

Musculoskeletal involvement by syphilis (Chapter 295) includes monoarticular or oligoarticular arthritis, polyarthralgias, tenosynovitis, sacroiliitis, spondylitis, chondritis, osteitis, and periostitis. Charcot joints, osteitis, and chronic arthritis are typical of tertiary syphilis. Arthritis may complicate congenital, secondary, and tertiary syphilis. Most patients with syphilis-related arthritis can be treated successfully (see Table 295-4).

PROSTHETIC JOINT INFECTION

More than 1 million joint replacements (Chapter 255) are performed each year in the United States, and this number continues to increase. Infection occurs in 0.3 to 1.7% of hip arthroplasties and 0.8 to 1.9% of knee arthroplasties. The risk of infection is two-fold to three-fold higher in patients with rheumatoid arthritis. Prosthetic joint infections are classified as (1) early infections, occurring within 3 months of joint replacement; (2) delayed infections, occurring 3 months to about 1 year after joint replacement; and (3) late infections, occurring more than 1 to 2 years after joint replacement. Infections occurring within the first year are usually related to the implantation surgery itself, and late infections are usually due to hematogenous spread.

Risk factors associated with the development of prosthetic joint infection include wound healing complications, prior superficial surgical site infection, prior infection of the joint, previous surgery on the joint, rheumatoid arthritis, advanced age, obesity, smoking, cancer, and diabetes mellitus. Other risk factors include simultaneous bilateral arthroplasty, prolonged operative time, requirement for blood transfusion, and infection occurring elsewhere in the body that can hematogenously seed the prosthesis.

The development of a bacterial biofilm on the prosthetic joint is characteristic of prosthetic joint infection. These biofilms are formed by bacterial glycocalyx, which increases the organisms' resistance to antimicrobial agents and likely accounts for the difficulty in obtaining viable organisms from the infected joint.

More than half of all prosthetic joint infections of hips and knees are caused by staphylococci. Other organisms, including gram-negative bacilli, anaerobes, and *Candida* species, may also cause infection. In particular, *Cutibacterium* species are commonly associated with infected shoulder arthroplasties. About 20% of cases are polymicrobial, and in 7%, cultures are negative.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with early-onset infection may have classic symptoms and signs of septic arthritis, including joint pain, effusion, erythema, fever, and poor wound healing. Patients with delayed infection may have only joint pain, with or without implant loosening, requiring a high degree of clinical suspicion for the presence of infection.

An elevated sedimentation rate or C-reactive protein without another obvious cause, such as inflammatory arthritis or recent surgery, is very suggestive of infection in a patient with a painful, loose prosthesis. Plain radiographs may show loosening, new bone formation, and lucencies along the implant margin but are often nonspecific. Technetium-based scintigraphy combined with indium-labeled white blood cell scanning is suggestive of established infection but is often not performed owing to the expense. MRI and CT have low utility in diagnosing prosthetic joint infection. Aspiration of the joint for synovial fluid leukocyte count, alpha defensin, and culture can be the most frequently used presurgical diagnostic test.[17]

The definitive diagnosis of prosthetic joint infection is based on the recovery of organisms from multiple specimens of synovial fluid and periprosthetic tissue, sonication of the prosthesis itself, acute inflammation suggestive of infection on pathologic examination of periprosthetic tissue obtained at surgery, or the presence of a sinus tract communicating with the prosthesis, even in the absence of microorganisms.

TREATMENT

Surgical treatment of prosthetic joint infection typically consists of débridement with retention of the prosthesis for acute infection, resection arthroplasty with or without staged reimplantation for chronic infection, or amputation in a few limited instances.[18,19] Systemic antibiotic therapy in a patient with a prosthetic joint infection is pathogen directed and driven by the surgical therapy used to manage the infection.[20] Following an attempt at salvage of prosthesis with 2 to 6 weeks of effective intravenous antibiotic therapy, chronic suppressive therapy with oral antimicrobial agents is often used. In rifampin-susceptible staphylococcal infections, its addition to a companion intravenous or oral antimicrobial is recommended to avoid the emergence of resistance, to treat biofilm organisms, and to improve the weeks of pathogen-directed intravenous therapy before an attempt at reimplantation several weeks later. The use of depot local antimicrobial therapy with antibiotic-impregnated polymethylmethacrylate spacers following resection arthroplasty is also very common. After an appropriate surgical procedure, 12 weeks of antibiotic therapy may be superior to 6 weeks, but about 10% of patients have persistent infection despite 12 weeks of antibiotics.[A3]

PREVENTION

In addition to optimizing comorbid conditions such as diabetes mellitus and discontinuing tobacco use preoperatively, careful screening for infection, including asymptomatic urinary tract infection, is prudent when considering joint surgery. Perioperative antibiotic treatment with a cephalosporin reduces the risk for infection in patients undergoing prosthetic joint replacement by approximately three-fold. Antimicrobial therapy should be given within 60 minutes of the initial incision, ideally before tourniquet application. Cefazolin or cefuroxime based on institutional guidelines can be given to patients with normal renal function, and vancomycin can be used in patients who are allergic to penicillin.

Whether an antirheumatic agent should be stopped before joint replacement surgery is unclear. The usual practice is to hold drugs such as anti-TNF

agents, and other biologics, including abatacept and tocilizumab, for one to four half-lives before and after surgery.

OSTEOMYELITIS

DEFINITION

Osteomyelitis is a bacterial infection of bone that causes destruction and can occur through a variety of mechanisms.

EPIDEMIOLOGY

Osteomyelitis of the bones of the foot in adult patients with diabetes (Chapter 210), neuropathy (Chapter 388), and arterial insufficiency (Chapters 65 and 66) is very common, often as the result of what would otherwise be minor trauma or skin infection in patients with normal sensation and circulation. Hematogenous seeding of the spine also occurs, but less frequently. The incidence of osteomyelitis due to trauma and surgery is increasing.

PATHOBIOLOGY

Osteomyelitis can develop from hematogenous seeding from a distant infection, contiguous spread from nearby skin and joints, and penetration of microorganisms into bone at the time of trauma or surgery. Except with trauma or the presence of a foreign body, bone is typically very resistant to infection. Organisms such as *S. aureus* (Chapter 267) cause disease more frequently because they colonize the skin in up to 30 to 40% of individuals, frequently cause cellulitis and bacteremia, and have the ability to bind to bone through the expression of receptors for fibronectin and collagen.[21]

Elderly individuals and injection drug users are susceptible to hematogenous causes of osteomyelitis, usually involving two or more vertebrae and their intervening disc spaces. Bacteria gain access to these structures through the arterial and venous systems (Batson venous plexus). Bacteremia from any source can cause osteomyelitis of the spine, but injection of contaminated substances, cellulitis, urinary tract infection, and pneumonia are the most common sources. Salmonella osteomyelitis (Chapter 284) is a complication of hematogenous spread, commonly in the absence of gastrointestinal symptoms.[22]

Contiguous focus osteomyelitis is common in adults, typically occurring in the elderly. It results from the spread of infection from nearby skin, often in the feet of patients with diabetes, neuropathy, or vascular insufficiency, or in pelvic bones in patients with decubitus ulcers due to impaired sensation from spinal cord injury or disease. Alternatively, it can occur with orthopedic surgery, from contamination at the time of an open fracture, or from a human or animal bite.

Acute osteomyelitis has a duration of less than 10 days, whereas chronic infection has a duration of more than 10 days. *S. aureus* is the most common cause of hematogenous and contiguous osteomyelitis in adults. Osteomyelitis due to β-hemolytic streptococci and aerobic gram-negative bacilli is much less common, but can occur if infections caused by these organisms result in hematogenous seeding, if nosocomial contiguous osteomyelitis occurs as a result of surgical site infection, or if contamination occurs at the time of traumatic open fracture. Polymicrobial infection, including infection caused by anaerobes, is very common in osteomyelitis of the bones of the feet associated with diabetes and vascular insufficiency. Coagulase-negative staphylococci can be pathogenic in patients with orthopedic implants.

CLINICAL MANIFESTATIONS

Localized pain over the affected bones is a hallmark of osteomyelitis. A sinus tract or swelling and erythema resulting from concomitant soft tissue infection or abscess may be present in osteomyelitis secondary to contiguous infection. Constitutional symptoms, including fever, are present in the minority of cases and more often in hematogenous osteomyelitis. If neurologic structures are involved, neurologic signs and symptoms such as pain and weakness may be present. Signs and symptoms due to a coexisting infection that has caused hematogenous osteomyelitis may be present as well. The differential diagnosis of osteomyelitis includes diseases that can cause acute and chronic bone pain in adults, including osteoarthritis (Chapter 241), metastatic malignancy, fractures, and SAPHO (*s*ynovitis, *a*cne, *p*ustulosis, *h*yperostosis, and *o*steitis) syndrome, as well as postoperative pain and soft tissue infection without concomitant osteomyelitis.

DIAGNOSIS

The WBC count is often elevated in hematogenous and acute osteomyelitis. Serum inflammatory markers such as the erythrocyte sedimentation rate and C-reactive protein are often abnormal, particularly in cases of hematogenous infection, but may be normal in chronic contiguous osteomyelitis. Blood cultures are positive in 25 to 50% of cases of hematogenous infection but are almost always negative in chronic osteomyelitis unless concomitant soft tissue infection is present. In the setting of chronic contiguous osteomyelitis, plain radiographs often show specific abnormalities; they are often not helpful in confirming the diagnosis of vertebral osteomyelitis.

The ability to probe percutaneously or to palpate bone with a probe (a sterile metal probe is inserted into the ulcer, and the test is positive if a hard, gritty surface is felt) is a simple, effective diagnostic test in patients with diabetes mellitus and possible contiguous osteomyelitis of the feet. For example, the probe-to-bone test has a sensitivity of 87% and a specificity of 83% for diagnosing foot osteomyelitis.

MRI is the most sensitive and diagnostic imaging technique to identify osteomyelitis,[23] except when orthopedic implants are present. Gallium scans are more sensitive and specific than three-phase technetium-99m (^{99m}Tc) bone scans or indium-labeled leukocyte scans for the diagnosis of vertebral osteomyelitis.[24] Gallium scans may be used when spinal hardware makes MRI less useful and in cases of skull bone osteomyelitis due to malignant external otitis.

Multiple specimens of involved bone, contiguous soft tissue, and purulence should be sent for Gram stain, aerobic and anaerobic culture, and pathologic examination at the time of bone biopsy or surgical débridement. If the history, examination, or imaging is suggestive of atypical infection, culture for fungi and mycobacteria or other unusual organisms should be performed.

TREATMENT

Antimicrobials for specific pathogens are recommended (see Table 251-2) based on in vitro susceptibility testing. Oral antibiotics can achieve adequate levels in bone,[25,26] and either oral or parenteral therapies can achieve similar cure rates.[A4] Dalbavancin (1500 mg intravenously on days 1 and 8) may be an alternative for gram-positive infections[A5] but should not be used routinely.

For diabetic foot osteomyelitis, surgical consultation is recommended. Medical therapy with or without limited surgical débridement is recommended in some cases of mild to moderate infection, although surgical resection is typically required for severe infection. The role of adjunctive rifampin in the treatment of diabetic foot infections is uncertain. Arterial revascularization may be required based on evaluation of the vascular supply to the affected limb.

The duration of antimicrobial therapy is almost always dictated by surgical therapy in chronic osteomyelitis. For example, only a short course of antimicrobial therapy may be required if an amputation is performed, whereas more prolonged intravenous or highly bioavailable oral antimicrobial therapy is typically recommended[27] if an extensive débridement of chronic osteomyelitis is performed, with data suggesting that 3 weeks is as good as 6 weeks.[A6] If the surgical therapy could lead to a worse outcome than no surgery, chronic oral antimicrobial suppression may be recommended. Acute hematogenous vertebral osteomyelitis in adults typically does not require surgical intervention but can be treated with 6 weeks of intravenous antimicrobial therapy, which is as good as 12 weeks of treatment in immunocompetent patients,[A7] after identification of the pathogen through percutaneous or open biopsy. Hyperbaric oxygen therapy for chronic osteomyelitis is controversial. Medical management is the mainstay of treatment of spinal tuberculosis (Chapter 299), with surgery indicated for specific situations.[28]

PREVENTION

Improving the control of diabetes and decreasing the incidence of peripheral vascular disease will reduce the incidence of diabetic foot bone infection. Optimal strategies to prevent surgical site infection after orthopedic procedures will prevent orthopedic implant infection after surgery and open fractures.

PROGNOSIS

The success of treatment depends on the medical and surgical therapy and the ability to improve comorbid conditions such as arterial insufficiency. The ability of orthopedic surgeons to perform more extensive reconstructive surgery has allowed more extensive débridement and higher success rates, as well as restoration of function. Treatment failure can lead to relapse of infection or progression of infection to involve more of the affected bone. Long-standing osteomyelitis can be complicated by amyloidosis, squamous cell carcinoma of the skin in a chronic sinus tract, or primary bone malignancy.

252 CRYSTAL DEPOSITION DISEASES

N. LAWRENCE EDWARDS

The three most common crystal-induced arthropathies are caused by precipitation of monosodium urate monohydrate, calcium pyrophosphate dihydrate, and basic calcium phosphate and are termed *gout, calcium pyrophosphate arthropathy*, and *basic calcium arthropathy*, respectively. Basic calcium crystals are ultramicroscopic in size and are not detected by the compensated polarized microscopy used to identify monosodium urate and calcium pyrophosphate dehydrate crystals. Like monosodium urate and calcium pyrophosphate crystals, basic calcium phosphate crystals are biologically active and can accelerate atrophic changes in bone and cartilage.

GOUT AND HYPERURICEMIA

DEFINITION

Gout is a metabolic disorder that results from the tissue deposition of monosodium urate crystals in or around joints and/or the crystallization of uric acid in the renal collecting system. Gout is the most common inflammatory joint disease in men and in older women. The metabolic derangement responsible for gout is the supersaturation of blood and body fluids with the urate ion to the point that crystal formation is possible. At physiologic pH and at normal body temperature, urate is considered to be supersaturated at concentrations of 6.8 mg/dL or greater. Therefore, from a biologic perspective, hyperuricemia is any serum urate level greater than 6.8 mg/dL in both men and women. Although hyperuricemia is a necessary prerequisite for developing gout, only 20% of all hyperuricemic subjects will ultimately develop gout.

EPIDEMIOLOGY

The incidence and prevalence of gout vary greatly throughout the world. In the United States, the United Kingdom, and much of Western Europe, the prevalence of gout ranges from 3 to 6% in men and 1 to 2% in women. In developing countries the prevalence is much lower, typically less than 1%. However, the highest prevalences have been noted in certain ethnic groups, especially in Oceanic populations, including Taiwanese Aborigines, Māori, and Pacific Islanders living in New Zealand, where prevalence estimates are more than 10%.[1,2] In Western societies, including the United States, the rate has more than doubled within the past three decades. Factors that have been proposed to explain this dramatic rise include the overall increase in longevity; the increased prevalence of hypertension, metabolic syndrome, and obesity; the increased use of thiazide diuretics and low-dose aspirin; changes in dietary trends, including the greater use of high-fructose corn syrup as a sweetener; and finally, the increase in survival of patients with end-stage renal disease and after organ transplantation.

The degree of elevation of the serum urate is directly correlated with the likelihood of developing gout. The reported annual incidence of gout in individuals with baseline serum urate levels of 9 mg/dL or higher is 4.9%, compared with only 0.5% in people with serum urate levels of 7.0 to 8.9 mg/dL.

PATHOBIOLOGY

Uric acid is the end product of purine metabolism in humans. Urate is produced by the conversion of a very soluble molecule, hypoxanthine, to the less soluble xanthine, which, in turn, is converted to the very insoluble uric acid by progressive purine ring oxidations catalyzed by the enzyme xanthine oxidase. Xanthine oxidase is present in several organs, but most activity in the body is found in the liver and intestines. In most mammals, purine catabolism is taken one step further through the enzyme uric acid oxidase or uricase, with the purine end product in these species being the very soluble allantoin. Humans and most other hominoids lost the ability to produce the enzyme uricase nearly 18 million years ago. As a result, uric acid accumulation is possible. Whether caused by overproduction of uric acid or its underexcretion by the kidneys, this accumulation leads to supersaturation of urate ion in blood and the precipitation of monosodium urate crystals in synovial fluid, soft tissues, and organs.

Because of urate's potential for causing disease, its elimination is very important. The total daily accumulation of uric acid from de novo synthesis, nucleotide degradation, and dietary consumption is normally balanced by renal excretion of approximately two thirds of the total urate turnover and by intestinal elimination of the remaining one third.

Hyperuricemia occurs when urate production is not balanced by renal excretion. In more than 90% of all patients with gout, the cause of this imbalance is renal underexcretion. Fewer than 10% of cases of gout are caused by the overproduction of purine or by a combination of overproduction and underexcretion. The nongenetic causes of hyperuricemia include other medical conditions, dietary components, and medications (Table 252-1). These factors may result in either overproduction or diminished renal clearance of uric acid. Similarly, the genetic causes of hyperuricemia (Table 252-2) may affect either production or elimination of uric acid.[3]

Renal Urate Underexcretion

Because uric acid is small and not protein bound, it is completely filtered by the glomerulus. In normal persons, approximately 8 to 10% of the filtered load is ultimately cleared in the urine. The various renal tubular transporters that are responsible for determining how much of the filtered uric acid is actually excreted are located in the proximal convoluted tubules and are referred to collectively as the *transportasome* (E-Fig. 252-1). Both reabsorption and secretion occur in this segment through the actions of several organic acid transporters, with the net effect being the reabsorption of nearly 90% of the uric acid filtered at the glomerulus. These organic acid transporters are also responsible for eliminating organic acids other than uric acid as well as many commonly used medications. The most important tubular transporter of uric acid is *URAT1*. This transporter swaps urate ions for other monocarboxylate organic ions in both directions across the luminal membrane of proximal tubular cells. This system can be driven to reabsorb more uric acid from the tubular lumen by raising tubular epithelial concentrations of lactate, pyruvate, or the ketoacids acetoacetate and β-hydroxybutyrate. Certain drugs, when present in the tubular lumen, can displace uric acid from the transporter, thereby causing more uric acid to be lost in the urine. These uricosuric agents include probenecid.

TABLE 252-1 NONGENETIC CAUSES OF HYPERURICEMIA

IMPAIRED URIC ACID EXCRETION
Clinical Conditions
Reduced glomerular filtration rate
Hypertension
Obesity
Lead nephropathy
Drugs
Thiazide diuretics
Ethanol
Low-dose salicylates (0.06-3.0 g/day)
Cyclosporine
Tacrolimus
Levodopa
Angiotensin-converting-enzyme inhibitors
β-Blockers
Nicotinic acid
Pancreatic extract
EXCESSIVE URIC ACID PRODUCTION
Clinical Conditions
Myeloproliferative and lymphoproliferative neoplasms
Obesity
Psoriasis
Diet Components
Alcoholic beverages (especially beer)
Red meat, organ meat, shellfish
High fructose corn syrup

252 CRYSTAL DEPOSITION DISEASES

N. LAWRENCE EDWARDS

The three most common crystal-induced arthropathies are caused by precipitation of monosodium urate monohydrate, calcium pyrophosphate dihydrate, and basic calcium phosphate and are termed *gout, calcium pyrophosphate arthropathy*, and *basic calcium arthropathy*, respectively. Basic calcium crystals are ultramicroscopic in size and are not detected by the compensated polarized microscopy used to identify monosodium urate and calcium pyrophosphate dehydrate crystals. Like monosodium urate and calcium pyrophosphate crystals, basic calcium phosphate crystals are biologically active and can accelerate atrophic changes in bone and cartilage.

GOUT AND HYPERURICEMIA

DEFINITION

Gout is a metabolic disorder that results from the tissue deposition of monosodium urate crystals in or around joints and/or the crystallization of uric acid in the renal collecting system. Gout is the most common inflammatory joint disease in men and in older women. The metabolic derangement responsible for gout is the supersaturation of blood and body fluids with the urate ion to the point that crystal formation is possible. At physiologic pH and at normal body temperature, urate is considered to be supersaturated at concentrations of 6.8 mg/dL or greater. Therefore, from a biologic perspective, hyperuricemia is any serum urate level greater than 6.8 mg/dL in both men and women. Although hyperuricemia is a necessary prerequisite for developing gout, only 20% of all hyperuricemic subjects will ultimately develop gout.

EPIDEMIOLOGY

The incidence and prevalence of gout vary greatly throughout the world. In the United States, the United Kingdom, and much of Western Europe, the prevalence of gout ranges from 3 to 6% in men and 1 to 2% in women. In developing countries the prevalence is much lower, typically less than 1%. However, the highest prevalences have been noted in certain ethnic groups, especially in Oceanic populations, including Taiwanese Aborigines, Māori, and Pacific Islanders living in New Zealand, where prevalence estimates are more than 10%.[1,2] In Western societies, including the United States, the rate has more than doubled within the past three decades. Factors that have been proposed to explain this dramatic rise include the overall increase in longevity; the increased prevalence of hypertension, metabolic syndrome, and obesity; the increased use of thiazide diuretics and low-dose aspirin; changes in dietary trends, including the greater use of high-fructose corn syrup as a sweetener; and finally, the increase in survival of patients with end-stage renal disease and after organ transplantation.

The degree of elevation of the serum urate is directly correlated with the likelihood of developing gout. The reported annual incidence of gout in individuals with baseline serum urate levels of 9 mg/dL or higher is 4.9%, compared with only 0.5% in people with serum urate levels of 7.0 to 8.9 mg/dL.

PATHOBIOLOGY

Uric acid is the end product of purine metabolism in humans. Urate is produced by the conversion of a very soluble molecule, hypoxanthine, to the less soluble xanthine, which, in turn, is converted to the very insoluble uric acid by progressive purine ring oxidations catalyzed by the enzyme xanthine oxidase. Xanthine oxidase is present in several organs, but most activity in the body is found in the liver and intestines. In most mammals, purine catabolism is taken one step further through the enzyme uric acid oxidase or uricase, with the purine end product in these species being the very soluble allantoin. Humans and most other hominoids lost the ability to produce the enzyme uricase nearly 18 million years ago. As a result, uric acid accumulation is possible. Whether caused by overproduction of uric acid or its underexcretion by the kidneys, this accumulation leads to supersaturation of urate ion in blood and the precipitation of monosodium urate crystals in synovial fluid, soft tissues, and organs.

Because of urate's potential for causing disease, its elimination is very important. The total daily accumulation of uric acid from de novo synthesis, nucleotide degradation, and dietary consumption is normally balanced by renal excretion of approximately two thirds of the total urate turnover and by intestinal elimination of the remaining one third.

Hyperuricemia occurs when urate production is not balanced by renal excretion. In more than 90% of all patients with gout, the cause of this imbalance is renal underexcretion. Fewer than 10% of cases of gout are caused by the overproduction of purine or by a combination of overproduction and underexcretion. The nongenetic causes of hyperuricemia include other medical conditions, dietary components, and medications (Table 252-1). These factors may result in either overproduction or diminished renal clearance of uric acid. Similarly, the genetic causes of hyperuricemia (Table 252-2) may affect either production or elimination of uric acid.[3]

Renal Urate Underexcretion

Because uric acid is small and not protein bound, it is completely filtered by the glomerulus. In normal persons, approximately 8 to 10% of the filtered load is ultimately cleared in the urine. The various renal tubular transporters that are responsible for determining how much of the filtered uric acid is actually excreted are located in the proximal convoluted tubules and are referred to collectively as the *transportasome* (E-Fig. 252-1). Both reabsorption and secretion occur in this segment through the actions of several organic acid transporters, with the net effect being the reabsorption of nearly 90% of the uric acid filtered at the glomerulus. These organic acid transporters are also responsible for eliminating organic acids other than uric acid as well as many commonly used medications. The most important tubular transporter of uric acid is *URAT1*. This transporter swaps urate ions for other monocarboxylate organic ions in both directions across the luminal membrane of proximal tubular cells. This system can be driven to reabsorb more uric acid from the tubular lumen by raising tubular epithelial concentrations of lactate, pyruvate, or the ketoacids acetoacetate and β-hydroxybutyrate. Certain drugs, when present in the tubular lumen, can displace uric acid from the transporter, thereby causing more uric acid to be lost in the urine. These uricosuric agents include probenecid.

ABSTRACT

The crystalline arthropathies are the most common causes of inflammatory arthritis in humans. Gouty arthritis is a disease of urate burden associated with the deposition of monosodium urate crystals in and around joints when the serum urate level exceeds its solubility concentration of 6.8 mg/dL. The presence of these crystals over time results in a severely painful inflammatory arthritis with destruction of bone and cartilage. Diagnostic confirmation of gout in a patient presenting with acute monoarthritis or oligoarthritis is made by synovial fluid aspiration demonstrating monosodium urate crystals on compensated, polarized microscopy or the classic ultrasound finding of the "double-contour sign." The therapeutic approach to gout requires the lowering of serum urate to below its solubility concentration so that resorption of the accumulated crystals can occur.

Calcium pyrophosphate disease is a heterogeneous condition that includes acute and chronic arthropathies and is closely associated with radiographic evidence of chondrocalcinosis. This condition can be familial or sporadic or can be a manifestation of an underlying metabolic disease. Basic calcium phosphate disease may, likewise, present as either an acute or chronic arthritis and is frequently associated with osteoarthritis. Milwaukee shoulder is the most destructive form of this basic calcium phosphate disease and occurs in the elderly. Treatment of these conditions is nonspecific and relies on nonsteroidal anti-inflammatory drugs and intra-articular glucocorticoids.

E-FIGURE 252-1. Renal transport of urate in proximal tubule of kidney. Serum urate reaches the tubule lumen by glomerular filtration and by secretion through the proximal tubular epithelium. Secretion of urate is facilitated in the luminal direction by MRP4, UAT, ABCG2, and NTP1, and at the basolateral membrane by OAT1 and OAT3. Reabsorption of urate from the tubular lumen is facilitated by URAT1, OAT4, OAT10, and the short isoform of GLUT (GLUT9b), and at the basolateral membrane by the long isoform (GLUT9a). ABCG2 = adenosine triphosphate–binding cassette transporter; GLUT = glucose transporter; MRP = multidrug-resistance-related protein; NTP = sodium phosphate transport protein; OAT = organic acid transporters; URAT = uric acid transporter.

TABLE 252-2 GENETIC CAUSES OF HYPERURICEMIA

SYNDROME	PHENOTYPE
INBORN ERRORS OF PURINE METABOLISM	
Hypoxanthine-guanine phosphoribosyl transferase deficiency	Neurologic dysfunction, renal stones, early-onset gout
Phosphoribosyl pyrophosphatase synthetase overactivity	Neurologic dysfunction, early-onset gout
EXCESSIVE CELL DEATH AND URATE GENERATION	
Glycogen storage disease I	Growth restriction, lactic acidosis, early-onset gout
Glycogen storage disease III	Early-onset gout
Glycogen storage disease V	Early-onset gout
Glycogen storage disease VII	Early-onset gout
Fructose-1-phosphate aldolase deficiency	Growth restriction, liver failure, early-onset gout
Myoadenylate deaminase deficiency	Myopathy, gout
Carnitine palmitoyltransferase II deficiency (late onset)	Rhabdomyolysis, gout
REDUCED RENAL EXCRETION OF URIC ACID	
Medullary cystic kidney disease	Renal dysfunction, early-onset gout
Familial juvenile hyperuricemic nephropathy	Renal dysfunction, early-onset gout
Uric acid transportasome mutations	
GLUT-9	Familial gout
ABCG2	Familial gout
URAT1	Familial gout

When the renal clearance of uric acid is compared between normal adult men and gouty men, the gouty subjects excrete only 70% as much uric acid as normal individuals at any given serum urate concentration. In general, gouty patients require a serum urate concentration to be 1.7 mg/dL higher to obtain the same level of excretion as seen in normal individuals.

Most genetic polymorphisms associated with gout in genome-wide association studies encode for the various components of the uric acid transportasome (see E-Fig. 252-1). Polymorphisms in the glucose transporter GLUT-9 (encoded by the *SLC2A9* gene) are statistically the most significant determinants of serum urate. ABCG2 is a multifunctional transporter that belongs to the adenosine triphosphate (ATP)-binding cassette family found primarily in the small intestine and liver.[4] Polymorphisms in the gene encoding URAT1 may lead to either hypouricemia or hyperuricemia. A loss-of-function mutation results in familial renal hypouricemia.

The serum urate variance explained by these common genetic variants is only about 6% of the total variance observed between gouty and non-gouty individuals. Similar risk-stratifying techniques demonstrate that 67% of the variance is caused by nongenetic factors such as the serum creatinine level, the consumption of ethanol, and the components of the metabolic syndrome.

Urate Overproduction

Traditionally, the causes of hyperuricemia were attributed to either the overproduction of urate or its underexcretion in the urine. The former was presumed to be the case when hyperuricemia occurred despite a 24-hour urinary uric acid collection showing more than 1000 mg while eating a standard Western diet. In many of these cases, the hyperuricemia reflects accelerated cell turnover (e.g., lymphoproliferative and myeloproliferative diseases, psoriasis, chronic hemolytic states, polycythemia vera, and certain muscle glycogenoses) or by enhanced breakdown of purine nucleotides (e.g., alcohol use disorder or ingestion of fructose). In addition to these secondary causes of urate overproduction, primary inborn errors of metabolism (e.g., phosphoribosyl pyrophosphate [PRPP] synthetase overactivity) can result in increased de novo purine synthesis, or decreased purine salvage (e.g., complete and partial hypoxanthine-guanine phosphoribosyltransferase [HPRT] deficiencies [Lesch-Nyhan syndrome and Kelley-Seegmiller syndrome, respectively]). Polymorphisms in the *ABCG2* urate transporter gene in the bowel can lead to extrarenal underexcretion of uric acid. This mechanism may account for a large percentage of cases previously considered to be due to overproduction of urate.

Pathogenesis of Monosodium Urate Monohydrate Crystals and Inflammation

Monosodium urate crystals in joints, soft tissues, and organs are the cause of pain and destruction in gout. Urate crystals will form only when physiologic conditions permit. In plasma, urate becomes insoluble at concentrations of 6.8 mg/dL (408 μmol/L) with a pH of 7.40 and normal body temperature. A reduction in pH or temperature will lower the solubility threshold even further. Not all people who are hyperuricemic will form crystals, however, and genetic factors other than those responsible for hyperuricemia affect when crystallization will occur.

Monosodium urate crystals form in joints and soft tissues of individuals long before they cause any symptoms of gout. Crystals deposit in small lattice structures called *microtophi* on the surface of cartilage and synovial lining. These microtophi slowly grow but are generally stable as long as the environment surrounding them does not change drastically with regard to pH, urate concentration, or temperature. At the time of the first and subsequent flares, these crystal lattice structures break apart and shed a massive number of crystals into the joint space. These newly released and nonopsonized crystals, which are not coated with albumin or immunoglobulins, activate receptors on synovial macrophages and are then phagocytized by monocytes and macrophages, thereby leading to the cytoplasmic assembly and activation of the NLRP3 inflammasome. The resulting rapid production of interleukin-1β is responsible for gout's cardinal features of severe inflammation.

Although monocytes and macrophages are the major cellular sources of IL-1β, neutrophils predominate at the site of inflammation (e.g., joint), where monosodium urate crystals become extremely pro-inflammatory by recruiting neutrophils that then generate reactive oxygen species. However, neutrophils also have a major role in the resolution of acute gout through the formation of neutrophil extracellular traps (NETs). Neutrophil proteases are released into the NETs and cause the formation of cell aggregates that contain cellular debris and DNA. These cellular aggregates within NETs can rapidly degrade pro-inflammatory cytokines, thereby allowing for the spontaneous resolution of joint inflammation after 3 to 6 days, even in the absence of treatment.[5]

CLINICAL MANIFESTATIONS

Classic Gout

The natural course of classic gout progresses through three stages: asymptomatic hyperuricemia, acute intermittent symptoms, and chronic persistent symptoms.[6] The rate of progression from initial symptoms to persistent symptoms varies considerably from one person to another and is dependent on numerous factors, the most important being the degree of increase in serum urate levels.

Asymptomatic hyperuricemia refers to a state in which serum urate exceeds the level of solubility (6.8 mg/dL) but symptoms of crystalline deposition have not occurred. Only 20% of all hyperuricemic people will ultimately develop monosodium urate crystals and gout. For this group, the period of asymptomatic hyperuricemia begins a stage of subclinical structural changes. In men, asymptomatic hyperuricemia frequently begins at puberty, whereas in women, it is usually delayed until menopause.

The initial clinical manifestations of gout usually follow decades of asymptomatic hyperuricemia. In men, the first flare usually occurs between the fourth and sixth decades of life. In women, the age of onset is older and varies with several factors, most importantly the age of menopause. The classic gout flare is hallmarked by the rapid development of warmth, swelling, erythema, and exquisite pain in one or occasionally two joints. The characteristically severe pain evolves from its faintest twinge to its most intense level over an 8- to 12-hour period. Initial episodes are usually monoarticular and involve lower extremity joints. The most commonly involved joint is the first metatarsal phalangeal joint (termed *podagra*), followed by the ankle, midfoot, and knee (Fig. 252-1). After years of recurrent gouty flares in the lower extremity joints, gout can involve upper extremity joints, including the wrists, elbows, and small joints of the hands.

Systemic symptoms of flares can include fever, chills, and malaise, with an intense erythema extending beyond the area of the involved joint. These symptoms and signs may lead to confusion with an infectious process.

Certain factors can provoke gouty flares by causing fluctuations in serum urate levels. Examples include trauma, surgery, starvation, bedrest, overindulgence in certain high-purine foods and beer, and the ingestion of any medication that raises or lowers serum urate.

Another characteristic of classic gout flares is their self-remitting nature. For the first several acute flares, the duration of the attack is 4 to 7 days. The resolution of symptoms is gradual but complete, even if no anti-inflammatory therapy is administered. The periods between the flares are devoid of articular pain, although synovial fluid aspirates during this stage continue to show low-grade inflammation and the presence of monosodium urate crystals.

Advanced Gout

Eventually, the untreated patient will progress to persistent gouty arthritis, also referred to as *advanced gout*. This stage usually develops after 10 or more

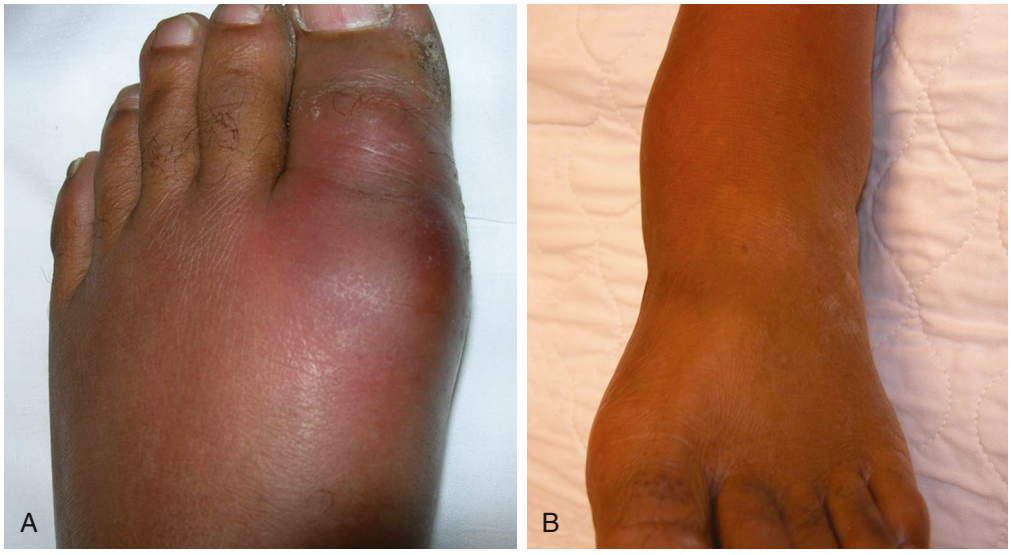

FIGURE 252-1. **The intense inflammation of acute gouty arthritis. A,** The marked swelling of the first metatarsophalangeal joint (podagra) is demonstrated. A dusky blue hue over an intense erythema is characteristic. **B,** Ankle swelling is shown with erythema extending beyond the area of the tibiotalar joint.

FIGURE 252-2. **Characteristic locations of gouty tophi. A,** At the elbow, tophi present as hard nodules along the ulnar ridge or as multiple nodules within the olecranon bursa. **B,** Ear tophi are uncommon but may be an easy source of crystal confirmation of gout when present. **C,** Small subcutaneous tophi can occur along the ventral creases of fingers. **D,** Tophi over the proximal interphalangeal or distal interphalangeal joints may be confused with Bouchard or Heberden nodes, respectively.

years of acute intermittent gout and is evident when the pain-free intercritical periods have disappeared. Gouty flares can continue to occur against this constantly painful background. The intensity of the chronic pain is not nearly as severe as that experienced with the acute flares.

The subcutaneous tophus is the most characteristic lesion of advanced gout. The development of tophaceous deposits of monosodium urate is a function of the duration and severity of hyperuricemia as well as the presence of proteinuria. Subcutaneous tophi may occur anywhere over the body but most commonly in the fingers, wrists, ears, knees, and olecranon bursa, as well as at pressure points under the ulnar aspect of the forearm and Achilles tendon (Fig. 252-2). At this stage, gout can be confused with rheumatoid arthritis (Chapter 243), especially if tophi are misdiagnosed as rheumatoid nodules.

Atypical Gout Presentations

Approximately 5% of patients with gout exhibit the onset of symptoms before age 25 years. Early-onset gout represents a special subset of patients who generally have a genetic component (see Table 252-2), with a more accelerated clinical course requiring more aggressive uric acid lowering therapy.

Women account for no more than 5% of all gout subjects, and most women with gout are postmenopausal. Premenopausal women who have gout usually have a strong genetic predilection or have renal insufficiency and hypertension and are taking thiazide diuretics. Gout in older women may differ from classic gout in its propensity to occur in joints previously damaged by osteoarthritis (Chapter 241), such as the knees or the distal interphalangeal joints with Heberden nodes.

DIAGNOSIS

Hyperuricemia is an essential risk factor for developing gout, but it is not a reliable diagnostic test because many people with elevated serum urate levels will never develop gout. Serum urate levels during an acute flare of gout are also unreliable because they may be suppressed by as much as 1.5 to 2.0 mg/dL from baseline values. The definitive diagnosis of gout is made by polarized compensated microscopy of a synovial fluid aspirate from the affected joint (Fig. 252-3).[7] The presence of intracellular needle-shaped crystals with strong negative birefringence is the diagnostic "gold standard." Similar microscopic results from a tophus aspirate or spontaneously draining fluid also confirm the diagnosis of gout.

However, synovial fluid confirmation is obtained in as few as 10% of patients said to have gout. In most cases, the presumptive diagnosis of gout is based on a pattern of acute joint symptoms coupled with the patient's own medical history or a family history. The characteristic clinical presentation is the rapid onset (over 8 to 12 hours) of severe pain in one or several lower extremity joints (especially the great toe, midfoot, and ankle). Other key features include joint erythema, difficulty walking, resolution by 2 weeks, presence of a tophus, and history of involvement of the first metatarsophalangeal joint. The presumptive diagnosis is given much greater credence if there have been similar previous attacks that spontaneously resolved to a symptom-free state. The patient's medical history also may reveal comorbid conditions frequently associated with gout or the use of medications associated with urate retention.

Radiographic evaluation is not helpful in the early phase of gout except to exclude a fracture. In advanced gout, affected joints may show punched-out periarticular erosions with classic overhanging edges. Ultrasonography can detect monosodium urate crystals layered over articular cartilage in early disease and may be diagnostic (Fig. 252-4). Magnetic resonance imaging is not part of a standard evaluation but will reveal soft tissue and intra-articular tophi long before they become clinically evident.

The differential diagnosis of acute gout includes bacterial infection (Chapter 251), trauma, sarcoidosis, and calcium pyrophosphate arthropathy (pseudogout). Diseases occasionally confused with advanced gout include rheumatoid arthritis (Chapter 243), reactive arthritis (Chapters 244 and 254), and calcium pyrophosphate arthropathy.

TREATMENT AND PREVENTION

Gouty Flare

The treatment goal for gouty flare is to relieve pain and terminate the flare as quickly as possible. Resting the painful joint and applying ice are generally helpful, but pharmacologic intervention is usually necessary to alter the excruciatingly painful course that may last for several days to more than a week. The therapeutic options include nonsteroidal anti-inflammatory drugs (NSAIDs; Table 26-4),[A1] oral colchicine,[A2] and corticosteroids.[A3] NSAIDs are widely used and generally cause fewer side effects than colchicine[A4] but may be inappropriate for patients who have renal insufficiency or peptic ulcer disease or who are on chronic anticoagulation. Oral colchicine administered as 1.2 mg (two tablets) at the time of flare onset followed in 1 hour by a third 0.6-mg tablet is the recommended dosing for the first 24 hours, followed by 7 to 10 days of once-daily or twice-daily colchicine depending on renal function. This regimen for colchicine in the acute flares situation should not be used in patients chronically taking colchicine for prophylaxis. Corticosteroids can be administered orally (e.g., prednisolone, 30 mg once a day), intramuscularly, or intra-articularly for acute gout symptoms and are valuable options in patients with poor renal function or intolerance to colchicine, and are of similar efficacy and slightly safer than NSAIDs (naproxen or indomethacin) for the treatment of active, acute gout.[A5]

Issues critical to treatment success for a gouty flare are the early initiation of treatment, ensuring adequate dosing of anti-inflammatory therapy, and continuing the treatment until the flare has completely resolved (usually 6 to 10 days). During the acute flare, patients who are already taking urate-lowering therapy should continue the drug without interruption. Patients who have an acute flare can safely be started on urate-lowering therapy during the flare as long as the anti-inflammatory medication is continued for the next several months.

Chronic Urate-Lowering Therapies

The principal goal of treating gout is to lower the serum uric acid below its saturation point so that the process of crystallization will cease and the accumulated urate burden will be gradually diminished. Guidelines[8–10] recommend a "treat-to-target" approach, using a xanthine oxidase inhibitor to reduce serum uric acid levels to less than 6.0 mg/dL in patients with a history of two or more clinical flares or a single flare if the person has chronic kidney disease (Chapter 116)

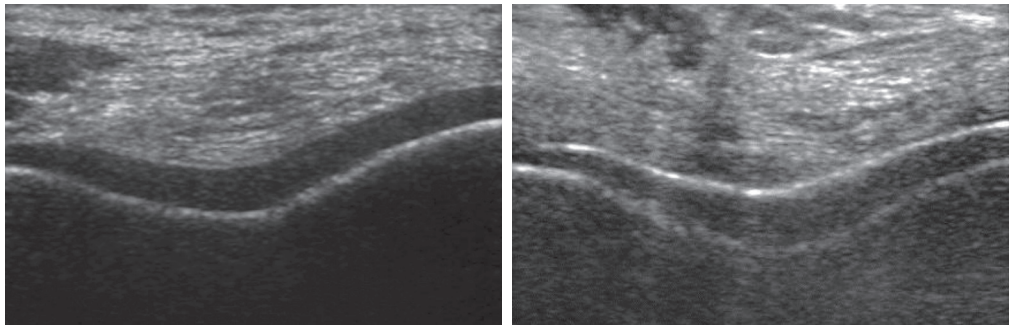

FIGURE 252-4. Double contour sign. Comparison of ultrasonographic appearance of normal (*left*) and gouty (*right*) knee with the probe in the suprapatellar, transverse orientation and the knee in flexion. The normal knee shows soft tissues overlying an anechoic *(black)* layer that represents hyaline cartilage. The single bright stripe represents the bony cortex of the anterior distal femur. The gouty knee demonstrated the "double-contour" sign composed of a layer of crystals covering the hyaline cartilage and the lower bright contour being the femoral cortex.

TABLE 252-3 SPECIFIC AMERICAN COLLEGE OF RHEUMATOLOGY RECOMMENDATIONS ON LIFESTYLE AND DIET FOR GOUTY PATIENTS

Weight loss for obese patients	Avoid: Organ meats High fructose corn syrup–sweetened drinks Alcohol overuse
Healthy overall diet	Limit: Beef, pork, lamb, shellfish Beer
Exercise to achieve fitness	Encourage: Low-fat dairy
Smoking cessation	
Stay well-hydrated	

stage 3 or greater and a serum urate of 9 mg/dL or greater.[A6,A7] An even lower target (<5.0 mg/dL) is recommended for patients with more advanced gout. Allopurinol is the first-line urate-lowering therapy, with the starting dose no greater than 100 mg/day. The dose is gradually escalated by 100 mg daily every 2 to 5 weeks, to a maximum dose of 800 mg daily, while monitoring the serum urate level until the target serum urate is achieved.[A8] In patients who have advanced chronic kidney disease, the initial dose should be 50 mg daily, with incremental dose escalations of 50 mg.

Febuxostat is an alternative urate-lowering therapy and should be used in patients who have failed allopurinol treatment or have demonstrated sensitivity or intolerance to allopurinol.[A9,11] The initial febuxostat dose of 20 to 40 mg daily can be gradually increased to 80 mg daily over the next 2 to 6 weeks of therapy if the serum urate target is not achieved. In gout patients with coexisting cardiovascular disease, overall rates of major cardiovascular events are probably similar in patients treated with febuxostat and allopurinol, although one study showed that overall mortality from any cause was more frequent with febuxostat.[A10,A11]

In patients who have gout but who have not attained the target serum urate despite maximal doses of either allopurinol or febuxostat, a uricosuric agent (e.g., probenecid, up to 2 g daily) can be added to the xanthine oxidase inhibitor. Uricosuric agents should be avoided in patients who have nephrolithiasis or have chronic kidney disease stage 4 or greater. Pegloticase (8 mg by IV infusion every 2 weeks) is an intravenously administered monomethoxypoly (ethylene glycol)-conjugated recombinant uricase that dramatically lowers serum urate levels. It is approved by the FDA for the treatment of gout in patients for whom conventional therapy has been ineffective. Pegloticase can be much more effective and less immunogenic if immunomodulatory co-therapy (methotrexate or mycophenolate mofetil) is given under expert guidance. Although not prescribed specifically for the prevention of gouty flares, empagliflozin significantly reduces uric acid and gout attacks when used in patients with heart failure.[A12]

Before the initiation of any form of urate-lowering therapy, the patient should be placed on anti-inflammatory therapy to prevent or minimize the anticipated increase in flare activity that is associated with starting urate-lowering therapy.[A13] Background anti-inflammatory prophylaxis is in the form of colchicine once or twice daily or low-dose NSAIDs. Anti-inflammatory prophylaxis should be continued for at least 3 to 6 months after initiation of urate lowering therapy and CBC and renal function should be followed during this time.

A heavy emphasis on patient education is important to obtain an optimal treatment outcome.[12] Not only should patients be informed about dietary and other lifestyle changes, such as weight loss,[A14] that will lower their serum uric acid and lessen flares (Table 252-3), but they should also know that their disease is caused by an excessive burden of monosodium urate crystals already present in their joints and soft tissues. This understanding of the disease process underlying gouty arthritis will help shift the focus from symptoms to "urate burden" as the real target of treatment.

CALCIUM PYROPHOSPHATE DIHYDRATE CRYSTAL DEPOSITION DISEASE

DEFINITIONS

The heterogeneous group of clinical conditions associated with calcium pyrophosphate dehydrate crystals are collectively called *calcium pyrophosphate crystal deposition disease*. Within this spectrum is the common radiographic finding of chondrocalcinosis that is frequently asymptomatic. The acute synovitis associated with intra-articular calcium pyrophosphate crystals can closely mimic the findings of gout and is hence referred to as *pseudogout*. The more chronic changes associated with calcium pyrophosphate-induced bone and cartilage destruction is referred to as *pyrophosphate arthropathy*. These conditions are further classified as familial (genetic), metabolic, and sporadic.

EPIDEMIOLOGY

The true prevalence of calcium pyrophosphate crystal deposition disease is unknown, but it is generally thought to be underdiagnosed because of its confusion with other forms of arthritis.[13] Radiographically appearing chondrocalcinosis is clearly an age-related phenomenon. Chondrocalcinosis of the meniscal and articular cartilage of the knee is seen in 4% of people between the ages of 55 and 59 years, in 18% of person ages 80 to 84 years, and in approximately 27% of individuals older than age 85 years.

PATHOBIOLOGY

Clinical calcium pyrophosphate disease is divided into three categories based on the etiology of altered inorganic pyrophosphate metabolism.[14] The categories are hereditary (familial), sporadic (idiopathic), and metabolic. All three types of calcium pyrophosphate disease are associated with the accumulation of extracellular inorganic pyrophosphate around chondrocytes, and extracellular inorganic pyrophosphate is necessary for the formation of calcium pyrophosphate crystals.

Hereditary forms of calcium pyrophosphate crystal deposition disease may be caused by increased transmembrane transport of chondrocytic intracellular inorganic pyrophosphate to its extracellular matrix because of diminished activity of the protective pyrophosphate hydrolases, or because of altered influences of factors that lead to increased extracellular inorganic pyrophosphate, including transforming growth factor-β, bone morphogenic protein-2 and -4, ascorbic acid, and osteopontin.

Transporter mutations are rarely observed in the sporadic form of calcium pyrophosphate disease. Aging chondrocytes in culture produce considerably more inorganic pyrophosphate than do younger chondrocytes, although the exact mechanism for this phenomenon is unclear.

The metabolic diseases that predispose to calcium pyrophosphate crystal deposition disease include hemochromatosis (Chapter 196), hyperparathyroidism (Chapter 227), hypomagnesemia (Chapter 105; as in Gitelman syndrome), and hypophosphatasia (Chapter 105). The result of these metabolic conditions is either increased extracellular inorganic pyrophosphate or alterations that are permissive for the formation of calcium pyrophosphate crystal in the cartilage matrix.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Calcium pyrophosphate crystal deposition disease presents in a variety of fashions. It is frequently asymptomatic (lanthanic) and recognized only by the appearance of chondrocalcinosis on radiographs.

The most common clinical manifestation accounting for approximately 60% of calcium pyrophosphate disease is a polyarticular arthritis affecting joints not typically involved in primary osteoarthritis (Chapter 241), including the wrists, shoulders, and metacarpophalangeal joints (particularly the second and third metacarpophalangeals). This form of calcium pyrophosphate disease is called *pseudo-osteoarthritis* and may be associated with occasional inflammatory attacks.

The acute monoarticular presentation of calcium phosphate deposition disease is known as pseudogout. The pain and swelling of pseudogout can be similar to that seen in gout. The onset is usually not as abrupt as with gout, and the attacks tend to persist for longer—frequently months. Pseudogout occurs more often in the large joints than in small joints. Calcium pyrophosphate crystal deposition disease also can occasionally present as a chronic polyarticular inflammatory disease that may mimic rheumatoid arthritis (Chapter 243) or polymyalgia rheumatica (Chapter 250).

Calcium pyrophosphate disease is diagnosed by identifying chondrocalcinosis by radiography in a patient with a clinical history suggestive of the disease (Fig. 252-5). Definitive diagnosis, when possible, is made by the finding of calcium pyrophosphate crystals by compensated polarized light microscopic examination of aspirated synovial fluid.

PREVENTION AND TREATMENT

No specific therapies are available for calcium pyrophosphate crystal deposition disease. In patients with metabolic disease–associated calcium pyrophosphate disease (e.g., hyperparathyroidism, hypomagnesemia, phosphotasia) other than hemochromatosis, treatment and control of the metabolic disease can afford some improvement in the arthritis.

For both the acute and chronic forms of calcium pyrophosphate crystal deposition disease, therapy is directed at symptoms.[15,16] Nonsteroidal anti-inflammatory drugs (NSAIDs; Table 26-4) are the mainstay of treatment. Low-dose oral colchicine (e.g., 0.6 mg twice daily) can be used in both acute and chronic settings. Intra-articular corticosteroids are also beneficial for symptomatic disease. The IL-1 inhibitor, anakinra, has been effectively used "off-label" by experts for treating calcium pyrophosphate disease flares.

FIGURE 252-5. Calcium pyrophosphate dihydrate arthropathy of the knee. Radiographic evidence of chondrocalcinosis showing fibrocartilage calcification as thick, linear deposits parallel to and separate from subchondral bone.

APATITE (BASIC CALCIUM PHOSPHATE)-ASSOCIATED ARTHROPATHY

Basic calcium phosphate crystals include several different crystal species, the most common of which is hydroxyapatite. The basic calcium phosphate crystals are unlike monosodium urate or calcium pyrophosphate crystals in that they are not identifiable by polarized microscopy. These very tiny crystals are responsible for several important clinical conditions. Although basic calcium phosphate crystals are found in 50% of osteoarthritic synovial fluids, the incidence and prevalence of the individual apatite-associated clinical manifestations have not been established, especially for the most severe and destructive apatite syndromes such as Milwaukee shoulder and tumoral calcinosis. The prevalence of the most common apatite-associated conditions, calcific periarthritis of the shoulder, is about 3%.

PATHOBIOLOGY

Basic calcium phosphate arthropathy can be idiopathic, hereditary, or related to an underlying condition such as hyperparathyroidism (Chapter 227), hypervitaminosis D (Chapter 199), sarcoidosis (Chapter 83), leukemia (Chapters 168 to 170), multiple myeloma (Chapter 173), or metastatic cancers (Chapters 164 and 227). As with monosodium urate and calcium pyrophosphate crystals, basic calcium phosphate crystals exert their pro-inflammatory effects by being phagocytized by resident synoviocytes and influxing leukocytes. Unlike monosodium urate and calcium pyrophosphate crystals, however, apatite crystals do not act through the *NLRP3* inflammasome. Rather, basic calcium phosphate crystals are dissolved in the acidic phagosome, raise intracellular calcium levels, and then activate the calcium-dependent signaling pathways. The synoviocytes are stimulated by these pathways to increase production of tumor necrosis factor-α and IL-6, and influxing neutrophils are stimulated to increase pro-inflammatory oxygen radicals. The fibroblasts in the joint lining and surrounding soft tissues are stimulated to increase production of many of the matrix metalloproteinases, such as collagenase 1, collagenase 3, and stromelysin 1.

Hypervitaminosis D
Sarcoidosis
Metastatic cancer
Myeloma
Leukemia

CLINICAL MANIFESTATIONS

The clinical manifestations of basic calcium phosphate deposition can be acute or chronic, and their cause can be idiopathic, hereditary, or secondary to other diseases that cause hypercalcemia (Table 252-4). Basic calcium phosphate crystals can be found in 50% of synovial fluids from osteoarthritic knees (Chapter 241). The presence of basic calcium phosphate crystals correlates with more severe radiographic changes secondary to more rapid deterioration in these osteoarthritic knees.[17] Acute inflammatory arthritis associated with basic calcium phosphate deposition is similar in many ways to that of gout and pseudogout and has been referred to as *pseudo-pseudogout*. The patients tend to be younger and usually have evidence of soft tissue basic calcium phosphate deposition elsewhere in the body. Periarticular calcifications are often asymptomatic. However, basic calcium phosphate deposition can cause an acute and severe inflammation of the ligaments, tendons, and bursae surrounding a joint, termed *acute calcific periarthritis*. Depositions frequently occur around the shoulders and hips but can also occur in fingers, toes, wrists, and ankles.

The most destructive basic calcium phosphate–associated arthropathy is Milwaukee shoulder, which is characterized by large, bloody noninflammatory effusions containing basic calcium phosphate crystals with or without calcium pyrophosphate crystals. The process results in the destruction of the rotator cuff, thereby leading to marked instability and glenohumeral cartilage dissolution. This process can also affect knees. As with the acute calcific periarthritis discussed previously, Milwaukee shoulder is observed in women four times more frequently than in men.

Diffuse idiopathic skeletal hyperostosis (DISH) is seen predominately in men and elderly individuals,[18] especially persons with obesity, diabetes, or the metabolic syndrome. The radiographic appearance of this condition is flowing ossifications along the anterolateral aspect of spinal vertebrae, especially in the thoracic spine. DISH is usually asymptomatic, but very large bridging osteophytes can cause stiffness and pain.[19] In the cervical spine, it can even result in dysphagia.[20]

Idiopathic tumoral calcinosis is rare but most prevalent in young Black patients, who develop large irregular calcifying masses in the soft tissue surrounding the shoulders, hips, and elbows. Some cases show a familial occurrence and medical conditions associated with hyperphosphatemia (Chapter 105).

TREATMENT AND PREVENTION

The treatment of most basic calcium phosphate–associated syndromes is conservative.[21] In acute inflammatory arthritis and periarthritis, low-dose oral colchicine (e.g., 0.6 mg twice daily) and NSAIDs (Table 26-4) are the mainstay of a symptomatic therapy. The persistent large effusion seen in Milwaukee shoulder should be serially aspirated to decrease intracapsular pressure. The added effectiveness of corticosteroid injections in this setting is unproved. The calcinosis associated with abnormal calcium and phosphate metabolism is best managed by treating the underlying metabolic process.

253 FIBROMYALGIA

DANIEL J. CLAUW

DEFINITION

Fibromyalgia is the term that describes chronic widespread musculoskeletal pain, for which no alternative cause can be identified. If fatigue rather than pain is the presenting complaint, individuals are often diagnosed with chronic fatigue syndrome.[1,2] Gastroenterologists often see the exact same patients and focus on their gastroenterologic complaints, and often use the terms functional gastrointestinal disorder, irritable bowel syndrome, nonulcer dyspepsia, noncardiac chest pain, or esophageal dysmotility to explain the patient's symptoms (Chapter 123). Neurologists see these patients for their headaches (Chapter 367) or unexplained facial pain, urologists for pelvic pain (Chapter 219) and urinary symptoms (and use labels such as interstitial cystitis, chronic prostatitis [Chapter 114], vulvodynia, and vulvar vestibulitis), dentists for temporomandibular disorders, and so on. Although many individuals will have only one "idiopathic" pain syndrome over the course of their lifetime, more often, individuals with one of these entities, as well as their family members, are likely to have several of these conditions. Newer terms to describe this group of conditions include chronic overlapping pain conditions or nociplastic pain.

EPIDEMIOLOGY

Chronic widespread pain is typically operationalized as pain above and below the waist, involving the left and right sides of the body, and also involving the axial skeleton. Population-based studies of chronic widespread pain suggest that roughly 4 to 12% of the population has this symptom at any given point in time.[3] Chronic regional pain is found in 20 to 25% of the population. Both chronic widespread and regional pain occur about 1.5 times more often in women than in men. These findings are very similar in different countries, ethnicities, and cultures.

Various types of environmental stressors, including but not limited to psychological factors, most likely trigger the development of fibromyalgia (Table 253-1). Fibromyalgia and related disorders are found at much higher than expected rates in individuals who have experienced specific infections (e.g., Epstein-Barr virus, Lyme disease, Q fever, viral hepatitis), and it is also likely that the long haul post-coronavirus disease (COVID) 2019 syndrome has significant nociplastic contributions.[4]

TABLE 253-1 STRESSORS CAPABLE OF TRIGGERING FIBROMYALGIA AND RELATED CONDITIONS

- Peripheral pain syndromes
- Infections (e.g., COVID, parvovirus, EBV, Lyme disease, Q fever, but not common upper respiratory infections)
- Physical trauma (automobile accidents)
- Psychological stress/distress
- Hormonal alterations (e.g., hypothyroidism)
- Drugs
- Vaccines
- Certain catastrophic events (war, but not natural disasters)

COVID = coronavirus disease 2019; EBV = Epstein-Barr virus.

Fibromyalgia is also more common after trauma (e.g., motor vehicle accidents) and wartime military service. It is also likely that part of the reason these different stressors can seemingly lead to worsening of fibromyalgia or fibromyalgia symptoms is because of how these stressors affect activity level, sleep, or overall distress, any of which then can lead to worsening of pain and other symptoms.

Secondary fibromyalgia is frequently found as a comorbid condition in other chronic pain conditions such as osteoarthritis and autoimmune rheumatic diseases. As many as 25% of patients correctly diagnosed with generalized inflammatory disorders such as systemic lupus erythematosus, rheumatoid arthritis, and ankylosing spondylitis will also fulfill diagnostic criteria for fibromyalgia. However, in clinical practice this co-expression often goes unrecognized, especially when the fibromyalgia develops after the autoimmune disorder or regional pain syndrome. In this setting when comorbid fibromyalgia goes unrecognized, patients are often unnecessarily treated more aggressively with potentially toxic biologics and immunosuppressive agents.

The "primary" form of fibromyalgia is also associated with serious comorbid conditions, with early life and ongoing stressors. Many if not most such patients have a lifetime history of a psychiatric disorder such as depression or anxiety (Chapter 362). There is typically more psychiatric and psychological comorbidity noted in individuals who are refractory to treatment. The bidirectional relationship between fibromyalgia and psychiatric conditions is likely due at least in part to common triggers to both sets of conditions, as well as shared pathophysiology. Potentially modifiable risk factors for developing fibromyalgia or worsening its course include poor sleep, obesity, physical inactivity, and job or life dissatisfaction. Cognitive factors such as catastrophizing (irrational thinking that the pain is much worse or more serious than it actually is) or fear of movement have been found to be poor prognostic factors in fibromyalgia and other chronic pain states.

PATHOBIOLOGY

Contemporary terms used to describe conditions such as fibromyalgia, irritable bowel syndrome, temporomandibular disorders, chronic fatigue syndrome, vulvodynia, and many other entities include "centralized pain" or "central sensitization" to imply that the central nervous system (CNS) is playing a prominent role in amplifying or causing the pain in most individuals with these syndromes (Table 253-2). Although peripheral nociceptive input might be involved for some such pain, CNS factors are probably amplifying it, thereby leading to other associated symptoms such as fatigue, memory problems, and disturbances of sleep and mood.[5] Many of these findings also have been noted in chronic fatigue syndrome, but the various pathophysiologic theories of chronic fatigue syndrome vary widely and are the source of considerable contention.

Genetic Factors

The strong familial predisposition to fibromyalgia and other chronic pain conditions has led many to study specific genetic polymorphisms that may be associated with a higher risk of developing fibromyalgia. First, candidate gene studies showed that genetic findings such as the serotonin 5-HT2A receptor polymorphism T/T phenotype, serotonin transporter, dopamine 4 receptor, and catecholamine *o*-methyl transferase (COMT) polymorphisms all were noted in higher frequency in fibromyalgia patients than in controls.

253 FIBROMYALGIA

DANIEL J. CLAUW

DEFINITION

Fibromyalgia is the term that describes chronic widespread musculoskeletal pain, for which no alternative cause can be identified. If fatigue rather than pain is the presenting complaint, individuals are often diagnosed with chronic fatigue syndrome.[1,2] Gastroenterologists often see the exact same patients and focus on their gastroenterologic complaints, and often use the terms functional gastrointestinal disorder, irritable bowel syndrome, nonulcer dyspepsia, noncardiac chest pain, or esophageal dysmotility to explain the patient's symptoms (Chapter 123). Neurologists see these patients for their headaches (Chapter 367) or unexplained facial pain, urologists for pelvic pain (Chapter 219) and urinary symptoms (and use labels such as interstitial cystitis, chronic prostatitis [Chapter 114], vulvodynia, and vulvar vestibulitis), dentists for temporomandibular disorders, and so on. Although many individuals will have only one "idiopathic" pain syndrome over the course of their lifetime, more often, individuals with one of these entities, as well as their family members, are likely to have several of these conditions. Newer terms to describe this group of conditions include chronic overlapping pain conditions or nociplastic pain.

EPIDEMIOLOGY

Chronic widespread pain is typically operationalized as pain above and below the waist, involving the left and right sides of the body, and also involving the axial skeleton. Population-based studies of chronic widespread pain suggest that roughly 4 to 12% of the population has this symptom at any given point in time.[3] Chronic regional pain is found in 20 to 25% of the population. Both chronic widespread and regional pain occur about 1.5 times more often in women than in men. These findings are very similar in different countries, ethnicities, and cultures.

Various types of environmental stressors, including but not limited to psychological factors, most likely trigger the development of fibromyalgia (Table 253-1). Fibromyalgia and related disorders are found at much higher than expected rates in individuals who have experienced specific infections (e.g., Epstein-Barr virus, Lyme disease, Q fever, viral hepatitis), and it is also likely that the long haul post-coronavirus disease (COVID) 2019 syndrome has significant nociplastic contributions.[4]

TABLE 253-1 STRESSORS CAPABLE OF TRIGGERING FIBROMYALGIA AND RELATED CONDITIONS

- Peripheral pain syndromes
- Infections (e.g., COVID, parvovirus, EBV, Lyme disease, Q fever, but not common upper respiratory infections)
- Physical trauma (automobile accidents)
- Psychological stress/distress
- Hormonal alterations (e.g., hypothyroidism)
- Drugs
- Vaccines
- Certain catastrophic events (war, but not natural disasters)

COVID = coronavirus disease 2019; EBV = Epstein-Barr virus.

Fibromyalgia is also more common after trauma (e.g., motor vehicle accidents) and wartime military service. It is also likely that part of the reason these different stressors can seemingly lead to worsening of fibromyalgia or fibromyalgia symptoms is because of how these stressors affect activity level, sleep, or overall distress, any of which then can lead to worsening of pain and other symptoms.

Secondary fibromyalgia is frequently found as a comorbid condition in other chronic pain conditions such as osteoarthritis and autoimmune rheumatic diseases. As many as 25% of patients correctly diagnosed with generalized inflammatory disorders such as systemic lupus erythematosus, rheumatoid arthritis, and ankylosing spondylitis will also fulfill diagnostic criteria for fibromyalgia. However, in clinical practice this co-expression often goes unrecognized, especially when the fibromyalgia develops after the autoimmune disorder or regional pain syndrome. In this setting when comorbid fibromyalgia goes unrecognized, patients are often unnecessarily treated more aggressively with potentially toxic biologics and immunosuppressive agents.

The "primary" form of fibromyalgia is also associated with serious comorbid conditions, with early life and ongoing stressors. Many if not most such patients have a lifetime history of a psychiatric disorder such as depression or anxiety (Chapter 362). There is typically more psychiatric and psychological comorbidity noted in individuals who are refractory to treatment. The bidirectional relationship between fibromyalgia and psychiatric conditions is likely due at least in part to common triggers to both sets of conditions, as well as shared pathophysiology. Potentially modifiable risk factors for developing fibromyalgia or worsening its course include poor sleep, obesity, physical inactivity, and job or life dissatisfaction. Cognitive factors such as catastrophizing (irrational thinking that the pain is much worse or more serious than it actually is) or fear of movement have been found to be poor prognostic factors in fibromyalgia and other chronic pain states.

PATHOBIOLOGY

Contemporary terms used to describe conditions such as fibromyalgia, irritable bowel syndrome, temporomandibular disorders, chronic fatigue syndrome, vulvodynia, and many other entities include "centralized pain" or "central sensitization" to imply that the central nervous system (CNS) is playing a prominent role in amplifying or causing the pain in most individuals with these syndromes (Table 253-2). Although peripheral nociceptive input might be involved for some such pain, CNS factors are probably amplifying it, thereby leading to other associated symptoms such as fatigue, memory problems, and disturbances of sleep and mood.[5] Many of these findings also have been noted in chronic fatigue syndrome, but the various pathophysiologic theories of chronic fatigue syndrome vary widely and are the source of considerable contention.

Genetic Factors

The strong familial predisposition to fibromyalgia and other chronic pain conditions has led many to study specific genetic polymorphisms that may be associated with a higher risk of developing fibromyalgia. First, candidate gene studies showed that genetic findings such as the serotonin 5-HT2A receptor polymorphism T/T phenotype, serotonin transporter, dopamine 4 receptor, and catecholamine *o*-methyl transferase (COMT) polymorphisms all were noted in higher frequency in fibromyalgia patients than in controls.

ABSTRACT

Fibromyalgia and chronic fatigue syndrome are two of many nociplastic pain disorders characterized by widespread body pain and comorbid symptoms, such as fatigue, sleep, and memory problems. Whereas the diagnosis and label of fibromyalgia has been controversial in the medical community for some time, it is now among the best studied pain conditions, with strong evidence of prominent involvement of the central nervous system (CNS), and best treated with therapies aimed at the CNS. Treatment of these conditions should include patient education, as well as a combination of nonopioid medications, behavioral therapies, lifestyle changes, and integrative treatments, as appropriate.

KEYWORDS

fibromyalgia
nociplastic pain
centralized pain
central sensitization
chronic fatigue syndrome
myofascial pain

TABLE 253-2 MECHANISTIC CHARACTERIZATION OF PAIN

	NOCICEPTIVE	NEUROPATHIC	CENTRALIZED/NOCIPLASTIC
Cause	Inflammation or damage	Nerve damage or entrapment	CNS or systemic problem
Clinical features	Pain is well localized, consistent effect of activity on pain	Follows distribution of peripheral nerves (i.e., dermatome or stocking/glove), episodic, lancinating, numbness, tingling	Pain is widespread and accompanied by fatigue, sleep, memory and/or mood difficulties, as well as history of previous pain elsewhere in body
Screening tools		PainDETECT	Body map or fibromyalgia survey
Treatment	NSAIDs, injections, surgery, opioids	Local treatments aimed at nerve (surgery, injections, topical) or CNS-acting drugs	CNS-acting drugs, nonpharmacologic therapies
Classic examples	Osteoarthritis Autoimmune disorders Cancer pain	Diabetic painful neuropathy Post-herpetic neuralgia Sciatica, carpal tunnel syndrome	Fibromyalgia Functional GI disorders Temporomandibular disorder Tension headache Interstitial cystitis, bladder pain syndrome

Variable degrees of any mechanism can contribute in any disease.
CNS = central nervous system; GI = gastrointestinal; NSAIDs = nonsteroidal anti-inflammatory drugs.

Subsequent studies confirmed some of these associations, whereas others did not. Subsequent larger genome-wide linkage and candidate gene studies identified other putative targets. The linkage studies confirmed the strong genetic contribution to fibromyalgia and suggested linkage of fibromyalgia to the chromosome 17p11.2-q11.2 region. The large candidate gene study identified significant differences in allele frequencies between cases and controls that were observed for three genes: *GABRB3, TAAR1,* and *GBP1*. In light of the fact that classic genetic studies have not yet identified strong, reproducible polymorphisms or haplotypes associated with fibromyalgia, and because there is clear evidence of environmental factors such as stress playing a prominent role in the pathogenesis, other groups have postulated that epigenetic findings might be important in fibromyalgia.

Disturbances in Pain and Sensory Processing

The pathophysiologic hallmark of fibromyalgia is augmented central pain processing. Individuals with fibromyalgia are more tender everywhere in the body, not just in the 18 regions originally considered to be "tender points." Several potential mechanisms have been experimentally found to be potentially responsible for pain amplification in fibromyalgia, including a decrease in the activity of descending analgesic pathways, and a diffuse increase in the processing of all sensory stimuli (not just pain). Affected individuals have a CNS–mediated problem with augmented pain or sensory processing that is contributing to the pain and other somatic sensitivities the individual is experiencing, rather than simply a nociceptive focus confined to the region of the body where pain is currently being experienced.

Brain Imaging Studies

Functional, chemical, and structural brain neuroimaging studies have provided the best "objective" evidence that the pain of fibromyalgia and related pain amplification syndrome is "real." Functional MRI (fMRI) studies have demonstrated that in individuals with fibromyalgia the application of mild pressure or heat stimulus, which other individuals would sense as touch rather than pain, is experienced as pain. Individuals with or without fibromyalgia utilize similar brain activation patterns and brain areas involved in pain processing. The insula is a brain region that is consistently hyperactive and is likely to play a key pathogenic role in fibromyalgia and related conditions. This region has been noted to play a critical role in sensory integration, with the posterior insula serving a purer sensory role, and the anterior insula being associated with the emotional processing of sensations.

Patients with fibromyalgia have increased connectivity between brain regions involved in increasing pain transmission and neural networks not normally involved in pain. During a painful stimulus, connectivity is decreased between key antinociceptive regions and a region identified as a potential source of dysfunctional pain inhibition in fibromyalgia. Quantitative sensory testing studies have demonstrated that fibromyalgia patients are more sensitive to a number of sensory stimuli other than pain, and that machine learning paradigms using functional neuroimaging data can accurately distinguish fibromyalgia patients from individuals without fibromyalgia with over 90% accuracy. Some of these functional connectivity findings related to the insula and default mode network may be present early in life before children develop pain. Although conditions such as fibromyalgia have generally not been thought to have an immune basis, low-grade inflammation may exist in both the periphery and perhaps even the central nervous system.

Imaging techniques also have been used to identify the neurotransmitter abnormalities that may be "driving" the pain amplification seen in fibromyalgia and other chronic pain disorders. Decreased *mu* opioid receptor availability (possibly due to increased release of endogenous *mu* opioids) has been reported in fibromyalgia. This finding, as well as previous studies showing increases in endogenous opioids in the cerebrospinal fluid of fibromyalgia patients, has been suggested as evidence of why opioid analgesics appear not to be efficacious in fibromyalgia.

Using proton spectroscopy to probe other neurotransmitters, fibromyalgia patients have been shown to have increases in brain concentrations of the body's major excitatory neurotransmitter, glutamate, in pain processing regions such as the insula. Drugs such as pregabalin and gabapentin are likely working in part in fibromyalgia by reducing glutamatergic activity. Individuals who have fibromyalgia and who have the highest pretreatment levels of glutamate in the posterior insula are most likely to respond to pregabalin. When pregabalin leads to improvement in symptoms in these individuals, functional MRI normalizes, thereby suggesting that this neurotransmitter is playing a critical role in the pathogenesis of fibromyalgia at least in some individuals. These studies also help clarify why no single class of CNS analgesic is likely to be effective in every patient with pain of CNS origin.

The Role of Peripheral Factors

Peripheral factors also play an important role in the pathogenesis and treatment of many individuals with fibromyalgia. For example, some elements of the processes of central sensitization can be worsened or driven by ongoing nociceptive input. Many individuals who have fibromyalgia also have comorbid conditions that cause ongoing peripheral nociceptive input (e.g., myofascial pain, osteoarthritis, obesity). In fact, one of the major areas of study needed into these conditions is to try to differentiate which individuals with these phenomena are being driven from the CNS (top down) and which may be driven by ongoing peripheral nociceptive input (bottom up).

CLINICAL MANIFESTATIONS

The majority of patients with fibromyalgia develop their pain symptoms in multiple body regions early in life, frequently beginning in childhood or adolescence. Individuals who eventually progress to develop fibromyalgia are more likely to experience headaches, dysmenorrhea, temporomandibular disorders, chronic fatigue syndrome, myofascial pain, irritable bowel syndrome and other functional gastrointestinal disorders, interstitial cystitis/painful bladder syndrome, endometriosis, and other regional pain syndromes (particularly with back and neck pain). In many cases, what may appear to a health care provider to be an entirely new type of acute or subacute pain is in fact only another region of the body involved with pain. The concept is evolving among pain specialists that these "centralized" pain disorders actually represent a single lifelong disease with a spectrum of symptoms in different regions of the body over time.[6]

Other CNS-mediated symptoms that are seen commonly in fibromyalgia and related conditions include fatigue and sleep and memory issues. Subsets of individuals with any chronic pain condition (e.g., low back pain, osteoarthritis, autoimmune disorders, sickle cell disease, etc.) also have the same phenotypic features and underlying mechanisms as those seen in fibromyalgia. Many pain experts now think that much chronic pain itself is a neural disease and that many of the underlying mechanisms operative in these heretofore considered idiopathic or functional pain syndromes may be similar no matter whether that pain is present throughout the body (e.g., in fibromyalgia) or localized to the low back, the bowel, or the bladder.

DIAGNOSIS

A careful musculoskeletal history and examination remains the most important diagnostic test for individuals with chronic pain. Current diagnostic criteria for fibromyalgia (Table 253-3 and Fig. 253-1)[7] are simple to use and acknowledge the nonpain symptoms of fibromyalgia and centralized pain. Finally, in addition to these criteria being used with a cut point to diagnose someone with fibromyalgia, they also serve as a good measure of the presence and severity of fibromyalgia, or "fibromyalgianess." For example, in individuals with conditions such as rheumatoid arthritis (Chapter 243), low back pain (Chapter 26), or osteoarthritis (Chapter 241), an individual's fibromyalgia score is typically more predictive of pain and disability than are objective measures of the activity of these diseases, such as inflammation or joint damage.

TABLE 253-3 DEFINITION OF FIBROMYALGIA

Requires all of the following:
- Pain in at least 4 of 5 regions*
- Symptoms at a similar level for ≥3 months
- Widespread pain index† ≥7 and symptom severity scale score‡ ≥5 OR widespread pain index 4-6 and symptom severity scale score ≥9

*Five regions are: neck, upper back, lower back; left shoulder girdle, upper arm, lower arm; right shoulder girdle, upper arm, lower arm; left buttock/hip, upper leg, lower leg; and right buttock/hip, upper leg, lower leg.

†Number of pain locations among 19 possible locations: left shoulder girdle, right shoulder girdle, left upper arm, right upper arm, left lower arm, right lower arm, left hip (buttock), right hip (buttock), left upper leg, right upper leg, left lower leg, right lower leg, left jaw, right jaw, chest, abdomen, neck, upper back, lower back.

‡See Fig. 253-1.

Wolfe F, Clauw DJ, Fitzcharles MA, et al. 2016 Revisions to the 2010/2011 fibromyalgia diagnostic criteria. *Semin Arthritis Rheum*. 2016;46:319-329.

The pain of fibromyalgia is typically diffuse or multifocal, is difficult to localize, often waxes and wanes, and is frequently migratory in nature. These characteristics of centralized pain are quite different from nociceptive pain, in which both the location and severity of pain are typically more constant.[8] Patients may complain of discomfort when they are touched or when wearing tight clothing, and they may experience dysesthesias or paresthesias that accompany the pain, as is seen with neuropathic pain.

The physical examination is generally unremarkable in individuals with fibromyalgia, but it is helpful to assess for diffuse tenderness rather than on specific tender points. For example, individuals with fibromyalgia exhibit unusual sensitivity to the inflation of a blood pressure cuff. Assessing the pain thresholds in the hands and arms of any chronic pain patient can provide valuable diagnostic information, with diffuse tenderness over many areas being the expected finding.

Groups of individuals with conditions (e.g., fibromyalgia, chronic fatigue syndrome, irritable bowel syndrome, headache, and temporomandibular disorders) typically display disturbances in pain and sensory processing, including increased pain to normally painful stimuli or pain to normally nonpainful stimuli. This predilection can be identified in the patient's history (e.g., by asking about sensitivity to bright lights, odors, drugs) as well as by using quantitative sensory testing or functional neuroimaging. It is critical that clinicians seeing patients with chronic pain evaluate individuals for the presence of this nociplastic phenotype because it can dramatically affect which treatments will or will not work for a given individual with chronic pain.

Diagnostic Evaluation

No laboratory or imaging tests can distinguish the pain of fibromyalgia. The duration of time the patient has had symptoms should guide the intensity of the diagnostic evaluation. If the patient's symptoms have persisted for several years, minimal testing is required, whereas a more aggressive strategy should be used for acute or subacute onset of symptoms. Basic testing can be limited to complete blood count and routine serum chemistries, along with thyroid-stimulating hormone (TSH) and erythrocyte sedimentation rate (ESR). Serologic studies such as assays for antinuclear antibodies (ANAs) and rheumatoid factor are generally not needed unless clinical features are not characteristic of fibromyalgia or abnormalities are found on physical examination.

Differential Diagnosis

Aside from the many comorbid conditions associated with fibromyalgia, it may present similarly to a number of disorders or concurrently with other disorders that may confuse the diagnosis (Table 253-4). Hypothyroidism (Chapter 207) and polymyalgia rheumatica (Chapter 250) can be differentiated from fibromyalgia by laboratory testing for thyroid-stimulating hormone and the erythrocyte sedimentation rate. Sleep apnea and hepatitis C also simulate fibromyalgia and tend to present more often in men than women.

Part I. Level of symptom severity over the past week:

Fatigue score (0-3) ___ Waking unrefreshed score (0-3) ___ Cognitive symptoms score (0-3) ___

where 0 = no problem; 1 = slight or mild problems, generally mild or intermittent; 2 = moderate, considerable problems, often present and/or at a moderate level; 3 = severe: pervasive, continuous, life-disturbing problems

Total (0-9): _____

Part II. Other symptoms experienced over the past six months:

Headaches (0-1) ___

Pain or cramps in lower abdomen (0-1) ___

Depression (0-1) ___ **Total (0-3): _____**

Final symptom severity scale score is sum of Part I and Part II scores: Total (0-12): _____

FIGURE 253-1. Symptom severity scale score for fibromyalgia. (Wolfe F, Clauw DJ, Fitzcharles MA, et al. 2016 Revisions to the 2010/2011 fibromyalgia diagnostic criteria. *Semin Arthritis Rheum*. 2016;46:319-329.)

TABLE 253-4 CONDITIONS THAT SIMULATE FIBROMYALGIA

COMMON
Hypothyroidism (Chapter 207)
Polymyalgia rheumatica (Chapter 250)
Early in course of autoimmune disorders (e.g., rheumatoid arthritis [Chapter 243] or systemic lupus erythematosus [Chapter 245])
Sjögren syndrome (Chapter 247)
LESS COMMON
Hepatitis C (Chapter 135)
Sleep apnea (Chapter 374)
Chiari malformation (Chapter 385)
Celiac sprue (Chapter 126)

TABLE 253-5 THERAPIES

PHARMACOLOGIC THERAPIES
• **Strong evidence:** tricyclics (amitriptyline, cyclobenzaprine); dual-reuptake inhibitors (SNRI—venlafaxine, duloxetine, milnacipran); alpha-2-delta ligands (pregabalin, gabapentin)
• **Modest evidence:** tramadol; selective serotonin reuptake inhibitors (SSRIs); low-dose naltrexone; cannabinoids; gamma hydroxybutyrate (GHB)
• **Weak evidence:** growth hormone, 5-hydroxytryptamine, tropisetron, S-adenosyl-L-methionine (SAMe)
• **Not shown to be effective:** opioids, NSAIDs, corticosteroids, benzodiazepine and nonbenzodiazepine hypnotics, melatonin, guaifenesin, dehydroepiandrosterone
NONPHARMACOLOGIC THERAPIES
• **Strong evidence:** cardiovascular exercise, cognitive behavior therapy, patient education, multidisciplinary therapy
• **Modest evidence:** strength training, Tai Chi, yoga, mindfulness, hypnotherapy, biofeedback, balneotherapy
• **Weak evidence:** acupuncture, chiropractic, manual and massage therapy, electrotherapy, ultrasound
• **No evidence:** tender (trigger) point injections, flexibility exercise

NSAID = nonsteroidal anti-inflammatory drug; SNRI = serotonin-norepinephrine reuptake inhibitor; SSRI = selective serotonin reuptake inhibitor.

If the individual is tender only over the interphalangeal joints but not the other regions, and especially if there are additional inflammatory signs (e.g., swelling, erythema, warmth) associated with the tenderness, there should be more concern about a systemic autoimmune rheumatologic disorder. If tenderness is confined to only the bones, one might suspect a metabolic bone disease (Chapter 224) or condition causing periostitis (e.g., hyperparathyroidism; Chapter 227).

Affirming the Diagnosis

Having excluded other potential disorders in the differential diagnosis of the patient's pain, a somewhat important step in the management of fibromyalgia is asserting the diagnosis. Despite concerns that being "labeled" with fibromyalgia may in general cause more harm than good, nearly all existing studies suggest otherwise. The diagnosis of fibromyalgia is often a source of relief for the patient and leads to decreased health care utilization because of a reduction in referrals and if diagnostic testing to look for the cause of the pain.

TREATMENT

Similar types of therapies are efficacious for all nociceptive pain conditions, including both pharmacologic (e.g., tricyclic compounds, serotonin norepinephrine reuptake inhibitors, and gabapentinoids) and nonpharmacologic treatments (e.g., education, exercise, cognitive behavioral therapy). Conversely, individuals with these conditions typically do not respond to therapies that are effective when pain is caused by injury or inflammatory disorders of tissues (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs], opioids, local injections, or surgical procedures).

General Approach

Individuals who are diagnosed with fibromyalgia should receive basic education regarding this disorder.[9] Clinicians can provide this education in the context of their practice (e.g., with nurse educators or other allied health professionals) or electronically using websites and videos. This education should stress the importance of the patients' active role in their own management. Patients should be informed that some of the most effective therapies are nondrug interventions such as exercise, improving sleep, and reducing stress. Although recent treatment guidelines favor the use of nonpharmacologic versus pharmacologic therapies,[A1,A2] most patients will need some coordinated combination of pharmacologic and nonpharmacologic therapies (Table 253-5) to achieve meaningful improvement in symptoms and function.[10] In addition, pragmatic factors in routine practice (lack of availability or reimbursement, patient is unwilling to try these therapies until their symptoms are somewhat better controlled) sometimes make it impractical to rely primarily on nonpharmacologic treatment.[11]

Nonpharmacologic Therapies

Patients should be strongly encouraged to engage in nonpharmacologic therapies, especially exercise and mind-body practices. The best-studied nonpharmacologic therapies in fibromyalgia are cognitive behavioral therapy and exercise, both of which are efficacious.[A3,A4] These treatments can produce sustained (e.g., longer than 1 year) improvements, especially when an individual complies with the therapy.

For exercise, it is important to "start low, go slow." Exercise of different types (aerobic, stretching, strengthening) has been particularly well studied as a treatment of both chronic fatigue syndrome and fibromyalgia and has perhaps the strongest evidence base of any therapy. Exercise typically improves fatigue, pain, and function for these conditions. In chronic fatigue syndrome, graded exercise therapy has been similarly shown to be helpful. Many fibromyalgia, chronic fatigue syndrome, and other chronic pain patients tend to be sedentary. In these individuals it might be more helpful to first focus on becoming more "active" rather than "exercising."

Among the different types of cognitive behavioral therapy, increased attention has focused on using behavioral measures to treat the sleep disorders (www.painguide.com), which play an important role in pain transmission. Self-help and adding emotional disclosure to standard cognitive behavioral therapy may be of benefit.[A5]

A number of other nonpharmacologic, complementary, and integrative therapies (e.g., mindfulness, Tai Chi, yoga, biofeedback, chiropractic manipulation, and acupuncture [Chapter 30]) may help patients assert a greater sense of control over their illness. Patients should be encouraged to choose the nonpharmacologic therapy that best resonates with their beliefs and is locally accessible.

Pharmacologic Therapy

A number of classes of drugs that can be of some benefit in fibromyalgia. However, as in other chronic pain conditions, drugs only work well in a subset of patients, and the overall effect size of any of these therapies for any type of chronic pain is small to modest at best.[12]

Tricyclic Agents

Low doses of tricyclic antidepressants—particularly amitriptyline,[A6] cyclobenzaprine, and mirtazapine[A7] (Table 362-5)—can help diminish symptoms of pain, poor sleep, and fatigue associated with fibromyalgia. Tolerability can be improved by starting with a very low dose (e.g., 10 mg of amitriptyline or 5 mg of cyclobenzaprine), giving the dose a few hours before bedtime, and then very slowly escalating the dose. Very-low-dose cyclobenzaprine is quite effective in a subset of fibromyalgia patients with the same sleep pattern.

Serotonin and Norepinephrine Reuptake Inhibitors

Selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, citalopram, and paroxetine (Table 362-5) can be useful, although the newer "highly selective" serotonin reuptake inhibitors (e.g., citalopram) appear to be less efficacious than the older SSRIs, which have some noradrenergic activity at higher doses.

Dual receptor serotonin-norepinephrine and norepinephrine-serotonin reuptake inhibitors (SNRIs and NSRIs; see Table 362-5) such as venlafaxine are often more effective than pure serotonergic drugs.[A8] Duloxetine[A9] and milnacipran are approved in the United States for the treatment of fibromyalgia, with studies generally noting modest improvement in clinical features such as pain, physical functioning, fatigue, and degree of reported physical impairment. For both compounds these effects appear to be largely unrelated to their effect on mood, thereby suggesting that the analgesic and other positive effects of this class of drugs in fibromyalgia are not simply due to their antidepressant effects. The maximum approved dose of duloxetine is 60 mg per day, but it was studied in trials at doses up to 120 mg and shown to be safe. Likewise, the initial dose of milnacipran is 100 mg, but some patients benefit from increasing the dose to as high as 200 mg. Hypertension is more likely to be a problem with milnacipran, because it appears to be more noradrenergic; for these same reasons it might

be slightly more likely to help with symptoms such as fatigue. Esreboxetine, a selective norepinephrine reuptake inhibitor, is also efficacious in fibromyalgia, but this drug is not approved for use at this time.

Anticonvulsants

Pregabalin is effective for pain, sleep disturbances, and fatigue in fibromyalgia.[A10] Gabapentin has similar efficacy and adverse effects profile in fibromyalgia.[A11] The tolerability of these drugs can be enhanced by starting at a low dose and giving either two thirds of the dose or the entire dose at bedtime. The maximally approved dose of pregabalin is 450 mg, but in trials it was studied at doses as high as 600 mg and shown to be safe and efficacious. For most patients, the gabapentin dose needed for analgesia is often 1800 to 2400 mg/day. Two other drugs that likely work similarly to the gabapentinoids by counteracting the effects of increased glutamatergic activity are memantine and ketamine, both of which have some evidence of efficacy. Another antiepileptic compound, clonazepam, has efficacy for treating temporomandibular disorder and associated jaw pain and is useful in the treatment of restless leg syndrome (Chapter 374) and thus may be of value in subsets of fibromyalgia patients with these comorbid conditions. In general, though, the risks associated with chronic benzodiazepine use likely outweigh the potential benefit.

Other CNS-Acting Drugs

Nonbenzodiazepine hypnotics, such as zopiclone and zolpidem can improve the sleep and, possibly, fatigue in fibromyalgia patients, but they have no significant effects on pain. Gamma-hydroxybutyrate (also known as sodium oxybate), a precursor of GABA with powerful sedative properties, can improve fatigue, sleep, and pain in patients with fibromyalgia. However, this drug is a scheduled substance in the United States because of its abuse potential and is not approved by the FDA because of safety concerns.

Many population-based studies show that the consumption of one drink per day of alcohol, which is a GABA agonist, may be protective against fibromyalgia. Not surprisingly, however, higher amounts of alcohol have adverse effects on pain. Cannabinoids are modestly efficacious for sleep and perhaps pain, but side effects are common.[A12]

Classic Analgesics

No adequate randomized controlled clinical trials have tested the efficacy of opioids for the pain of fibromyalgia, but they do not appear to be effective. In fact, imaging studies of patients with fibromyalgia suggest that the native state of fibromyalgia may be akin to opioid-induced hyperalgesia. Tramadol, a compound that has some opioid activity (weak μ-agonist activity), combined with serotonin/norepinephrine reuptake inhibition appears to be somewhat efficacious in the management of fibromyalgia, as both a single drug and in fixed-dose combination with acetaminophen.

A large number of fibromyalgia patients use nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, but analgesics are not effective for fibromyalgia when used as single agents.[A13] However, the combination of celecoxib and acyclovir may be effective in fibromyalgia,[A14] and patients may likewise experience enhanced analgesia when treated with combinations of NSAIDs and other agents.

Combination Medical Therapy

Combining multiple classes of adjunctive pain medications has been a common practice. For example, one study demonstrated that the combination of duloxetine and pregabalin was superior to either drug alone in treating fibromyalgia.[A15]

Interventional Therapies

Transcutaneous electrical nerve stimulation (TENS) has been used to treat musculoskeletal pain and may sometimes be helpful in fibromyalgia. Newer neurostimulatory therapies include noninvasive techniques such as repetitive transcranial magnetic stimulation (rTMS) and transcranial direct current stimulation (t-DCS). Outcomes with these therapies have yielded inconsistent results.[A16] More invasive approaches such as spinal cord stimulation, deep brain stimulation, and vagal nerve stimulation show promise in refractory pain states. Trigger-point injections can be useful for the treatment of localized myofascial pain, but there is no evidence that adding corticosteroids or even local anesthetics adds anything to their beneficial effect.

PROGNOSIS

Fibromyalgia is typically a chronic, often life-long condition that waxes and wanes. Long-term complications include a higher risk of unnecessary procedures, physical injuries, and suicide. Earlier recognition and successful treatment is likely to be necessary to prevent the significant functional disability that often accompanies fibromyalgia, since at present these individuals often go decades seeking a diagnosis and treatments that are helpful.

254 SYSTEMIC DISEASES IN WHICH ARTHRITIS IS A FEATURE

STERLING G. WEST AND S. LOUIS BRIDGES, JR.

Arthritis, arthralgias, and myalgias can be significant features of several systemic diseases and may be the presenting symptoms for some of these disorders (Table 254-1). Appropriate evaluation of these musculoskeletal symptoms, including selected laboratory tests and radiographs, can provide clues to the early diagnosis of these diseases. Synovial biopsies are rarely necessary but can be diagnostic. Because of the rarity of many of these diseases, evidence-based treatments with U.S. Food and Drug Administration–approved medications are lacking.

AUTOIMMUNE HEPATITIS

Patients with type I autoimmune hepatitis (Chapter 135) may present with a syndrome resembling systemic lupus erythematosus (Chapter 245).[1] Patients with the early-onset subset are frequently young and female, with complaints of polyarthralgia and occasionally various rashes and/or fever. Laboratory examination may show leukopenia, a positive antinuclear antibody (70 to 90%), elevated erythrocyte sedimentation rate, polyclonal gammopathy, and elevated liver-associated enzymes. Hypocomplementemia and antibodies against double-stranded DNA are usually not seen, whereas antibodies against the smooth muscle antigen (F1 actin) support the diagnosis.[2] Joint radiographs show soft tissue swelling without erosions or deformity. Joint pain resolves with corticosteroid therapy for the liver disease. Patients with autoimmune hepatitis have an increased risk for having a concurrent autoimmune disease, including Sjögren syndrome (Chapter 247), in about 7% of cases.

be slightly more likely to help with symptoms such as fatigue. Esreboxetine, a selective norepinephrine reuptake inhibitor, is also efficacious in fibromyalgia, but this drug is not approved for use at this time.

Anticonvulsants

Pregabalin is effective for pain, sleep disturbances, and fatigue in fibromyalgia.[A10] Gabapentin has similar efficacy and adverse effects profile in fibromyalgia.[A11] The tolerability of these drugs can be enhanced by starting at a low dose and giving either two thirds of the dose or the entire dose at bedtime. The maximally approved dose of pregabalin is 450 mg, but in trials it was studied at doses as high as 600 mg and shown to be safe and efficacious. For most patients, the gabapentin dose needed for analgesia is often 1800 to 2400 mg/day. Two other drugs that likely work similarly to the gabapentinoids by counteracting the effects of increased glutamatergic activity are memantine and ketamine, both of which have some evidence of efficacy. Another antiepileptic compound, clonazepam, has efficacy for treating temporomandibular disorder and associated jaw pain and is useful in the treatment of restless leg syndrome (Chapter 374) and thus may be of value in subsets of fibromyalgia patients with these comorbid conditions. In general, though, the risks associated with chronic benzodiazepine use likely outweigh the potential benefit.

Other CNS-Acting Drugs

Nonbenzodiazepine hypnotics, such as zopiclone and zolpidem can improve the sleep and, possibly, fatigue in fibromyalgia patients, but they have no significant effects on pain. Gamma-hydroxybutyrate (also known as sodium oxybate), a precursor of GABA with powerful sedative properties, can improve fatigue, sleep, and pain in patients with fibromyalgia. However, this drug is a scheduled substance in the United States because of its abuse potential and is not approved by the FDA because of safety concerns.

Many population-based studies show that the consumption of one drink per day of alcohol, which is a GABA agonist, may be protective against fibromyalgia. Not surprisingly, however, higher amounts of alcohol have adverse effects on pain. Cannabinoids are modestly efficacious for sleep and perhaps pain, but side effects are common.[A12]

Classic Analgesics

No adequate randomized controlled clinical trials have tested the efficacy of opioids for the pain of fibromyalgia, but they do not appear to be effective. In fact, imaging studies of patients with fibromyalgia suggest that the native state of fibromyalgia may be akin to opioid-induced hyperalgesia. Tramadol, a compound that has some opioid activity (weak μ-agonist activity), combined with serotonin/norepinephrine reuptake inhibition appears to be somewhat efficacious in the management of fibromyalgia, as both a single drug and in fixed-dose combination with acetaminophen.

A large number of fibromyalgia patients use nonsteroidal anti-inflammatory drugs (NSAIDs) and acetaminophen, but analgesics are not effective for fibromyalgia when used as single agents.[A13] However, the combination of celecoxib and acyclovir may be effective in fibromyalgia,[A14] and patients may likewise experience enhanced analgesia when treated with combinations of NSAIDs and other agents.

Combination Medical Therapy

Combining multiple classes of adjunctive pain medications has been a common practice. For example, one study demonstrated that the combination of duloxetine and pregabalin was superior to either drug alone in treating fibromyalgia.[A15]

Interventional Therapies

Transcutaneous electrical nerve stimulation (TENS) has been used to treat musculoskeletal pain and may sometimes be helpful in fibromyalgia. Newer neurostimulatory therapies include noninvasive techniques such as repetitive transcranial magnetic stimulation (rTMS) and transcranial direct current stimulation (t-DCS). Outcomes with these therapies have yielded inconsistent results.[A16] More invasive approaches such as spinal cord stimulation, deep brain stimulation, and vagal nerve stimulation show promise in refractory pain states. Trigger-point injections can be useful for the treatment of localized myofascial pain, but there is no evidence that adding corticosteroids or even local anesthetics adds anything to their beneficial effect.

PROGNOSIS

Fibromyalgia is typically a chronic, often life-long condition that waxes and wanes. Long-term complications include a higher risk of unnecessary procedures, physical injuries, and suicide. Earlier recognition and successful treatment is likely to be necessary to prevent the significant functional disability that often accompanies fibromyalgia, since at present these individuals often go decades seeking a diagnosis and treatments that are helpful.

254 SYSTEMIC DISEASES IN WHICH ARTHRITIS IS A FEATURE

STERLING G. WEST AND S. LOUIS BRIDGES, JR.

Arthritis, arthralgias, and myalgias can be significant features of several systemic diseases and may be the presenting symptoms for some of these disorders (Table 254-1). Appropriate evaluation of these musculoskeletal symptoms, including selected laboratory tests and radiographs, can provide clues to the early diagnosis of these diseases. Synovial biopsies are rarely necessary but can be diagnostic. Because of the rarity of many of these diseases, evidence-based treatments with U.S. Food and Drug Administration–approved medications are lacking.

AUTOIMMUNE HEPATITIS

Patients with type I autoimmune hepatitis (Chapter 135) may present with a syndrome resembling systemic lupus erythematosus (Chapter 245).[1] Patients with the early-onset subset are frequently young and female, with complaints of polyarthralgia and occasionally various rashes and/or fever. Laboratory examination may show leukopenia, a positive antinuclear antibody (70 to 90%), elevated erythrocyte sedimentation rate, polyclonal gammopathy, and elevated liver-associated enzymes. Hypocomplementemia and antibodies against double-stranded DNA are usually not seen, whereas antibodies against the smooth muscle antigen (F1 actin) support the diagnosis.[2] Joint radiographs show soft tissue swelling without erosions or deformity. Joint pain resolves with corticosteroid therapy for the liver disease. Patients with autoimmune hepatitis have an increased risk for having a concurrent autoimmune disease, including Sjögren syndrome (Chapter 247), in about 7% of cases.

ABSTRACT

Arthritis, arthralgias, and myalgias can be significant features of several systemic diseases and may be the presenting symptoms for some of these disorders. Appropriate evaluation of these musculoskeletal symptoms, including selected laboratory tests, radiographs, and occasionally biopsies, can provide clues to the early diagnosis of these diseases. Owing to the rarity of many of these diseases, therapy is often empiric because most treatments are not based on evidence.

KEYWORDS

Whipple disease
amyloid arthropathy
carcinomatous polyarthritis
sarcoid arthropathy

TABLE 254-1 SYSTEMIC DISEASES ASSOCIATED WITH ARTHRITIS

DISEASE	TEST*
GASTROINTESTINAL DISEASES	
Autoimmune hepatitis (Chapter 135)	Liver-associated enzymes, *ASMA*
Primary biliary cirrhosis (Chapter 141)	Alkaline phosphatase, *antimitochondrial Ab*
Inflammatory bowel disease (Chapter 127)	Fecal occult blood testing, fecal calprotectin, *colonoscopy*
Whipple disease (Chapter 305)	*Tissue biopsy, tissue immunohistochemical stain for Tropheryma whipplei, PCR for T. whipplei DNA*
Gluten-sensitive enteropathy (Chapter 126)	*Antitransglutaminase antibody, small bowel biopsy*
Pancreatitis-arthritis syndrome (Chapter 130)	Lipase, amylase, *abdominal CT scan*
Hepatitis B/hepatitis C (Chapter 135)	Liver-associated enzymes, *hepatitis serology, cryoglobulins*
Intestinal bypass arthritis	*Cryoglobulins*
HEMATOLOGIC DISORDERS	
Hemophilia (Chapter 160)	PTT, *factor VIII and IX levels*
Hemoglobinopathies (Chapter 149)	CBC, *hemoglobin electrophoresis*
Hypogammaglobulinemia (Chapter 231)	Low total protein, *SPEP, immunoglobulins*
Plasma cell dyscrasias (Chapter 173)	High total protein, *SPEP, UPEP, IEF*
ENDOCRINE DISORDERS	
Diabetes mellitus (Chapter 210)	Glucose, *hemoglobin* A_{1c}
Thyroid disorders (Chapter 207)	TSH, *thyroxine*
Parathyroid disorders (Chapter 227)	Calcium, phosphorus, *PTH*
Acromegaly (Chapter 205)	Radiographs, *growth hormone, IGF-I*
Hyperlipoproteinemia (Chapter 190)	Lipid panel
Paget disease (Chapter 228)	Bone-specific alkaline phosphatase, radiographs, *bone scan*
MALIGNANT DISORDERS	
Hypertrophic osteoarthropathy	Radiographs (hands, wrists, chest)
Leukemia and lymphoma (Chapters 168 to 172)	CBC, LDH, *bone marrow/tissue biopsy*
Carcinomatous polyarthritis	*Cancer screen*
Palmar fasciitis and arthritis	*CA-125, pelvic CT scan, cancer screen*
OTHER DISEASES	
Hemochromatosis (Chapter 196)	Iron studies, radiographs, *HFE gene*
Multicentric reticulohistiocytosis (Chapter 155)	Radiographs, *skin/synovial biopsy*
Sarcoidosis (Chapter 83)	Chest radiograph, *ACE level, tissue biopsy*
IgG4-related disease	Serum IgG4 level, *histopathology of biopsy specimens including IgG4 immunostaining*
Alkaptonuria (Chapter 189)	Radiographs, *urine homogentisic acid level*
Fabry disease (Chapter 191)	Angiokeratomas, *a-galactosidase A level or gene mutation*
Relapsing polychondritis (Chapter 239)	*Cartilage biopsy*
Cystic fibrosis (Chapter 77)	Chest radiograph, *sweat chloride, CFTR gene mutation*
Tenosynovial giant cell tumor: diffuse type (diffuse pigmented villonodular synovitis)	Synovial fluid analysis, *MRI, synovial biopsy*
Systemic infections	Cultures, serologies (RPR, HIV, EBV, parvovirus)

*Tests listed are common laboratory tests and radiographs that are frequently ordered; this information should provide a clue that a systemic disease is a possible cause of the patient's musculoskeletal symptoms. These tests, coupled with the history and physical examination, should be followed by more specific tests and biopsies (listed in italics) to confirm the diagnosis.

Ab = antibody; ACE = angiotensin-converting enzyme; ASMA = anti–smooth muscle antibody; CBC = complete blood cell count; CFTR = cystic fibrosis transmembrane conductance regulator; CT = computed tomography; EBV = Epstein-Barr virus; HIV = human immunodeficiency virus; IEF = immunoelectrophoresis; IGF-I= insulin-like growth factor-I; IgG4 = immunoglobulin G4; LDH = lactate dehydrogenase; MRI = magnetic resonance imaging; PCR = polymerase chain reaction; PTH = parathyroid hormone; PTT = partial thromboplastin time; RPR = rapid plasmin reagin; SPEP = serum protein electrophoresis; TSH = thyroid-stimulating hormone; UPEP = urine protein electrophoresis.

PRIMARY BILIARY CHOLANGITIS (CIRRHOSIS)

Up to 50% of patients with primary biliary cholangitis (PBC) (Chapter 141) have other autoimmune disorders, including rheumatoid arthritis, Sjögren syndrome, limited systemic sclerosis, systemic lupus erythematosus, and autoimmune thyroiditis.[3] In addition to antimitochondrial antibodies, rheumatoid factor, antinuclear antibodies, and anticentromere antibodies are often present. More than 10% of patients with primary biliary cholangitis have a symmetrical or asymmetrical small joint inflammatory arthritis. Unlike rheumatoid arthritis, it can involve distal interphalangeal joints and is rarely erosive or deforming. Other musculoskeletal manifestations include osteomalacia related to vitamin D deficiency, osteoporosis related to renal tubular acidosis, and hypertrophic osteoarthropathy associated with liver disease.

INFLAMMATORY BOWEL DISEASE

Musculoskeletal symptoms are the most frequent extraintestinal manifestation occurring in patients with inflammatory bowel disease[4] (ulcerative colitis and Crohn disease; Chapter 127). The pathogenesis of these musculoskeletal manifestations is complex and includes interactions among gut microbes, mucosal immunity, and a genetic predisposition. Symptoms occur most commonly in patients who have involvement of the large bowel. Two types of inflammatory peripheral arthritis occur in about 15% of patients. Type I arthropathy is an acute, remitting (<6 months), nondestructive oligoarthritis most commonly involving the knee. This arthritis occurs early or prior to onset of bowel symptoms and is often associated with flares of inflammatory bowel disease. Type II arthropathy tends to be a nondestructive polyarthritis involving both small (e.g., metacarpophalangeal) and large joints. This arthritis persists for months, has frequent relapses, and does not parallel the activity of inflammatory bowel disease. Sacroiliitis (10%) and ankylosing spondylitis (3%) present with buttock and spinal pain and stiffness. This axial spondyloarthropathy, which can occur alone or in association with type I arthropathy, is associated with HLA-B27 (in 50 to 75% of cases), and its clinical course is not related to the activity of the inflammatory bowel disease. Other possible rheumatic manifestations include dactylitis (0 to 6%), enthesitis, septic arthritis, and hypertrophic osteoarthropathy. Treatment of the underlying inflammatory bowel disease, including conventional synthetic and/or biologic disease-modifying drugs (Chapter 123), will improve the musculoskeletal manifestations.

WHIPPLE DISEASE

An inflammatory arthritis occurs in up to 80% of patients with Whipple disease (Chapter 305) and may precede the gastrointestinal manifestations by a median of 5.5 years.[5] The joint involvement is typically an intermittent, migratory oligoarthritis, which affects large joints more than small joints or the sacroiliac joints and which persists from several hours to days. The synovial fluid is inflammatory, with a predominance of mononuclear cells. Subcutaneous nodules are occasionally seen and may lead to an erroneous diagnosis of rheumatic fever or rheumatoid arthritis. However, patients consistently test negative for rheumatoid factor and antinuclear antibodies. Synovial biopsies show rod-shaped bacilli on electron microscopy, which have been identified as *Tropheryma whipplei*. Diagnosis is suspected when duodenal, synovial, or lymph node biopsies show periodic acid–Schiff–positive macrophages. Infection is confirmed by demonstration of the organism in tissue by immunohistochemical staining with antisera specific for *T. whipplei*. Quantitative polymerase chain reaction to detect *T. whipplei* DNA is used as a confirmatory test performed on tissue and body fluids. Typically, the arthritis does not cause radiographic changes or deformities. Prolonged antibiotic therapy results in resolution of musculoskeletal as well as other symptoms of this disease. Relapses, especially neurologic, can occur in up to 35% of patients after cessation of antibiotic therapy.

GLUTEN-SENSITIVE ENTEROPATHY (CELIAC DISEASE)

An asymmetrical oligoarthritis or symmetrical polyarthritis occurs in up to 25% of adults with celiac disease (Chapter 126). The arthritis may precede the enteropathic symptoms by months to years in up to 50% of cases. Large joints such as knees and ankles, more than hips and shoulders, are most commonly involved. Axial involvement is reported. The arthritis does not cause deformities or radiographic changes and resolves with a gluten-free diet in 40 to 50% of cases. Another musculoskeletal manifestation is osteomalacia (Chapter 226) related to vitamin D malabsorption, which may mimic diffuse fibromyalgia. Arthralgias due to gluten sensitivity without celiac disease are also reported.

PANCREATITIS-ARTHRITIS SYNDROME

Pancreatic panniculitis is a systemic syndrome occurring in some patients with pancreatic acinar cell carcinoma (Chapter 180) and less commonly in patients with pancreatitis (Chapter 130) or hematologic malignancies. Prominent fat necrosis is due to the release of lipase, amylase, and trypsin

from the diseased pancreas. This syndrome is characterized by tender red nodules, usually on the extremities; these lesions are frequently misdiagnosed as erythema nodosum, but biopsy shows areas of lobular panniculitis with fat necrosis. Arthritis occurs in 60% of patients and usually involves the ankles and knees. Other manifestations include osteolytic lesions (10%) from bone marrow fat necrosis, pleuropericarditis, fever, and eosinophilia. Magnetic resonance imaging (MRI) shows multifocal intraosseous fat necrosis and arthritis of the knees and feet.[6] Synovial fluid is typically noninflammatory and creamy in color. It contains multiple lipid droplets because of necrosis of fat in the synovial membrane.

HEMOPHILIA

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) (Chapter 160) are associated with hemarthrosis. Acute and chronic arthritis are less frequent and less severe in patients with hemophilia B compared with hemophilia A. Almost all patients with factor levels less than 1% of normal experience recurrent hemarthroses spontaneously or after minor trauma. Large joints (knees, elbows, ankles) are most commonly involved. Intramuscular hemorrhage can also occur. Recurrent hemarthrosis can lead to proliferative synovitis and cartilage degradation, thereby resulting in both erosive and degenerative changes on radiographs or ultrasonography.[7] Physical examination shows bone enlargement, crepitus, atrophic muscles, and joint contractures. Treatment of acute monoarthritis consists of factor replacement to achieve a level of 30% or greater, given at the first sign of joint swelling. Patients with fever (temperature >38° C) or who fail to respond to factor replacement need joint aspiration to exclude septic arthritis, which occurs with an increased incidence in hemophilia. Chronic arthritis is treated with COX-2 selective nonsteroidal anti-inflammatory drugs (NSAIDs; Table 26-4), which do not inhibit platelet function; arthroscopic or radiation synovectomy for chronic synovitis; and total joint arthroplasty for end-stage joint disease. Better preventative therapies have reduced the risk for developing chronic arthropathy.

HEMOGLOBINOPATHIES

Patients with sickle cell anemia (Chapter 149) or the heterozygous states of sickle β-thalassemia and sickle hemoglobin C disease frequently experience polyarthralgia.[8] Local sickling of cells leads to obstruction of the microcirculation and to bone infarctions. Patients most commonly experience painful crises causing chest, back, and joint pain, which can be caused or worsened by glucocorticoid therapy. A painful large joint arthritis (usually in the knees), which persists for days to 3 weeks, can also occur. Synovial effusions are usually noninflammatory but can be mildly inflammatory because of local phagocytosis of sickled cells. Infarcts in the metaphyses of bones are commonly found on joint radiographs. Vertebral bodies have a characteristic "Lincoln log" appearance or a central cuplike indentation ("codfish vertebrae"). Femoral and humeral head osteonecrosis can occur in up to 33% of patients with sickle cell anemia and sickle hemoglobin C disease. Because of splenic autoinfarction, septic arthritis (*Staphylococcus aureus*) and osteomyelitis (50% caused by *Salmonella*) have been associated with sickle cell disease. In adults, gout has been reported. Treatment includes intravenous hydration, oxygen, and analgesics. Hydroxyurea can reduce the frequency of painful crises. In patients with β-thalassemia major (Chapter 148), significant expansion of bone marrow, owing to increased erythroid precursors, leads to osteoporosis and microfractures that affect primarily the lower extremities. Chelation therapy with deferiprone to reduce iron overload from transfusions can cause arthralgias in 20% of patients.

HYPOGAMMAGLOBULINEMIA

Common variable immunodeficiency and selective immunoglobulin A (IgA) deficiency are the most common primary immunodeficiencies[9] (Chapter 231). Adults with common variable immunodeficiency can develop a nonerosive, noninfectious large joint oligoarthritis that responds to intravenous immunoglobulin therapy. However, septic arthritis caused by common pathogens or *Mycoplasma* can also occur and must be rigorously excluded. Autoimmune disorders, most commonly autoimmune cytopenias and pernicious anemia, occur in 30% of patients with common variable immunodeficiency and may be the presenting manifestation. Selective IgA deficiency (Chapter 231) is associated with various rheumatic manifestations, including positive autoantibodies, in the absence of clinical disease. Systemic autoimmune disorders, including systemic lupus erythematosus and organ-specific autoimmune disorders, such as type 1 diabetes mellitus and myasthenia gravis, also occur in IgA-deficient individuals.

AMYLOIDOSIS

Primary amyloidosis and myeloma-associated amyloidosis are plasma cell disorders with overproduction of monoclonal immunoglobulin light chains (Chapter 174) and their deposition in tissues. Amyloid deposits in the synovium can lead to rheumatic symptoms, which may be misdiagnosed as rheumatoid arthritis or polymyalgia rheumatica. Amyloid arthropathy occurs in up to 5% of myeloma patients and may be the initial manifestation.[10] Arthropathy affects both males and females at an average age of 60 years. Polyarthritis or oligoarthritis most commonly affects the shoulders, knees, wrists, and small joints of the hand. Subcutaneous nodules and carpal tunnel syndrome can be additional manifestations. The erythrocyte sedimentation rate is nearly always elevated, but rheumatoid factor and antinuclear antibodies are negative. Synovial fluid is usually normal or minimally inflammatory. Congo red staining of spun synovial fluid can show amyloid deposits from synovial fragments. Joint radiographs are nonerosive but may show lytic bone lesions. The arthritic symptoms do not respond to glucocorticoids or other anti-inflammatory medications.

DIABETES MELLITUS

A causal relationship between arthritis in general and diabetes mellitus is not established. However, certain specific musculoskeletal disorders are associated with diabetes.[11] Diabetic stiff hand syndrome of limited joint mobility (diabetic cheiroarthropathy) occurs in more than 30% of patients with long-standing, poorly controlled type 1 or type 2 diabetes mellitus (Chapter 210). Patients present with the insidious development of flexion contractures and thickened skin of the fingers, which may be confused with scleroderma. These changes may be due to excess glycosylation of tendinous structures and accumulation of sugar alcohols, which lead to excess water content in the tissues and increased stiffness. Additionally, intracellular hyperglycemia causes oxidative stress and the formation of advanced glycation end products, which damage vascular endothelium and form cross-links with skin and tendon collagen, thereby leading to biologic dysfunction. As a result of the inability to extend the fingers fully, the "prayer sign" is observed on physical examination. Unlike diabetic stiff hand syndrome, Dupuytren contractures are due to a chronic thickening of the palmar aponeurosis, with flexion deformities of primarily the fourth and fifth digits. Dupuytren is a frequent musculoskeletal complication, occurring in more than 20% of patients with type 2 diabetes.

A less common manifestation is neuropathic arthropathy (Charcot joints), which occur in less than 1% of all patients with long-standing diabetes annually. All patients have a diabetic peripheral neuropathy and typically present with painless swelling, usually of the foot, most commonly caused by destruction of the tarsometatarsal joints. Deformities can occur with midtarsal collapse ("rocker bottom" foot) and predispose to ulceration and infection of the skin over desensate bony prominences. Radiographs are diagnostic, and treatment should include supportive footwear and protected weight bearing.

Unlike neuropathic arthropathy (Charcot joint), diabetic osteolysis and diabetic amyotrophy are unique to diabetes. The osteolysis is characterized by resorption of the distal metatarsal bone and proximal phalanges of the feet, thereby giving radiographs a characteristic "licked candy" appearance. Pain is variable, and treatment is conservative because the process may terminate on its own.

Diabetic amyotrophy is a lumbar polyradiculopathy (L2 to L4) that arises with severe pain, dysesthesias, and rapid atrophy of the proximal muscles of one or both thighs. Carpal tunnel syndrome (20%), adhesive capsulitis of the shoulder (frozen shoulder) (20 to 30%), flexor tenosynovitis (trigger finger) of the hands (20%), diffuse idiopathic skeletal hyperostosis (type 2 diabetes), osteopenia (type 1 diabetes), diabetic muscle infarction (usually of the thigh), osteomyelitis of the foot, and septic joints are all musculoskeletal conditions that occur with increased frequency in diabetic patients. Aggressive control of blood glucose helps prevent some of these musculoskeletal complications.

THYROID DISORDERS

Musculoskeletal symptoms occur in 33% of patients with clinical hypothyroidism (thyroid-stimulating hormone levels >20 μU/mL) (Chapter 207). Patients can present with carpal tunnel syndrome, Raynaud phenomenon, or muscle aching and stiffness similar to fibromyalgia and polymyalgia rheumatica. Patients with severe hypothyroidism can experience a noninflammatory myopathy with proximal muscle weakness and an elevated creatine kinase level, which may be confused clinically with polymyositis. Similarly, myxedematous patients can develop a symmetrical arthropathy of the large joints, especially the knees, associated with noninflammatory synovial fluid with

increased viscosity. The association of hypothyroidism with chondrocalcinosis is controversial, but clearly patients beginning thyroid replacement therapy can experience an acute attack of pseudogout. Patients with hyperthyroidism can develop proximal myopathy (70%), adhesive capsulitis of the shoulder (10%), osteoporosis, or thyroid acropachy. Thyroid acropachy, which occurs in less than 1% of patients with Graves disease, consists of soft tissue swelling of the hands, digital clubbing, and periostitis, particularly involving the metacarpal and phalangeal bone shafts. Pain is usually mild, radiographs are characteristic, and there is no effective therapy. Patients with autoimmune thyroid disease have an increased prevalence of nonspecific arthralgias, positive antinuclear antibodies, and possibly an increased association with systemic autoimmune rheumatic diseases such as Sjögren syndrome.

PARATHYROID DISORDERS

Primary hyperparathyroidism (Chapter 227) can cause osteoporosis with fractures and/or chondrocalcinosis with episodes of acute pseudogout. In severe hyperparathyroidism, which is rare, vague myalgias and arthralgias resemble fibromyalgia, a reversible and painless proximal myopathy with a normal creatine kinase level can be seen, and osteitis fibrosa cystica with bone pain can develop. Osteitis fibrosa cystica occurs primarily in patients with secondary hyperparathyroidism associated with renal failure and has a characteristic radiographic appearance, with subperiosteal resorption on the radial side of the phalanges, small erosions in the hands and distal clavicles, and discrete lytic bone lesions (brown tumors). Ectopic calcifications, joint laxity, and tendon ruptures have been reported in patients with severe hyperparathyroidism. Hypoparathyroidism has also been associated with ectopic and perispinal ligament calcifications. Patients with types Ia and Ic pseudohypoparathyroidism and patients with pseudo-pseudohypoparathyroidism have a shortened fourth metacarpal bone bilaterally.[12]

ACROMEGALY

Up to 75% of patients with acromegaly (Chapter 205) develop an atypical form of osteoarthritis, which may be the presenting feature.[13] The knees, shoulders, hips, and lumbosacral and cervical spine are the most frequently symptomatic areas, although the hands reveal the most characteristic radiographic changes, with osteophytosis but, unlike primary osteoarthritis, widened joint spaces due to cartilage hypertrophy. Carpal tunnel syndrome (50%), Raynaud phenomenon (33%), diffuse idiopathic skeletal hyperostosis (20%), and proximal muscle weakness with a normal serum creatine kinase can also occur.

HYPERLIPOPROTEINEMIA

Type IIa familial hyperlipidemia (Chapter 190) is associated with tendinous and tuberous-osseous xanthomas as well as episodic Achilles tendinitis. An acute migratory, inflammatory arthritis/periarthritis persisting up to a month and resembling rheumatic fever occurs in 5 to 7% of patients. Predominantly large joints are affected. In addition, a self-limited, acute monoarticular or oligoarticular arthritis involving the knee or ankle can occur. Patients with type III familial hyperlipoproteinemia can develop tendon (Achilles, wrist, finger) and rarely bone xanthomas. Patients with human immunodeficiency virus (HIV) infection taking protease inhibitor drugs can develop dyslipidemia that leads to tendon xanthomas. In all hyperlipidemias, gout must be excluded before ascribing the symptoms to hyperlipoproteinemia.

PAGET DISEASE

Paget disease (Chapter 227) can cause bone pain and deformity.[14] An elevated bone-specific alkaline phosphatase and characteristic radiographic changes can help make the diagnosis. Joint pain caused by secondary osteoarthritis in areas of bone involvement by Paget disease most commonly occurs in the hips, knees, or vertebrae. Spinal stenosis from Paget disease of the spine has been reported. Bisphosphonate therapy (Chapter 225) is highly effective.

HYPERTROPHIC OSTEOARTHROPATHY

Hypertrophic osteoarthropathy is a syndrome that includes clubbing of the fingers and toes, periostitis of long bones (distal tibia, femur, radius), and arthritis (Fig. 254-1). Hypertrophic osteoarthropathy is classified into primary (associated with mutations in *HPGD* and *SLCO2A1*) and secondary forms.[15] Between 80 and 90% of secondary hypertrophic osteoarthropathy is associated with intrathoracic neoplasms, especially non–small cell lung cancer (Chapter 177). Other causes include other neoplasms, chronic pulmonary infections, congenital heart disease, cirrhosis, HIV infection, medications (voriconazole), and inflammatory bowel disease. Patients with secondary hypertrophic osteoarthropathy can present with acute, severe, burning bone pain and a noninflammatory arthritis caused by periarticular periostitis. Pain is accentuated by dependency of the limbs. Pitting edema, warmth, and tenderness of the legs and forearms can be seen. Radiographs show diagnostic changes of periosteal elevation, new bone formation, or both along the distal ends of long bones. Therapy is symptomatic with NSAIDs (Table 26-4). Hypertrophic osteoarthropathy improves with successful treatment of the underlying primary disease. In resistant cases, treatment with intravenous zoledronic acid (4 mg intravenously once) or octreotide (100 μg subcutaneously twice daily) has been effective in modulating symptoms.

LEUKEMIA AND LYMPHOMA

Leukemia can arise as an asymmetrical or migratory polyarthritis, monoarthritis (rare), back pain (10%), or nocturnal bone pain. Articular manifestations occur in 14 to 50% of children and 4 to 16% of adults with acute leukemia (Chapter 168) and can precede the diagnosis by months. Joint pain is attributed to leukemic synovial infiltration and usually involves the ankle or knee, but it can be polyarticular, resembling juvenile or adult rheumatoid arthritis. The joint pain is disproportionately more severe than the clinical findings. Synovial effusions are uncommon, and evidence of leukemic cells in the synovial fluid is rare. Bone pain due to subperiosteal leukemic cell infiltration occurs in up to 50% of patients, with long bone pain (lower extremities) more common in children and back pain more common in adults. Radiographs are normal in 50% of cases. The musculoskeletal symptoms are poorly responsive to NSAIDs but can resolve with successful therapy of the leukemia.

Musculoskeletal symptoms occur in 25% of patients with non-Hodgkin lymphoma (Chapter 171). Nocturnal bone pain is the most common presenting musculoskeletal complaint. A seronegative monoarthritis or polyarthritis can occur and should be suspected in patients with severe constitutional symptoms or lymphadenopathy out of proportion to the degree of arthritis.

Patients with angioimmunoblastic T-cell lymphoma may occasionally develop a chronic, nonerosive polyarthritis with erythroderma. Intravascular large B-cell lymphoma can present with arthralgias, a positive antinuclear antibody test, various skin lesions, and neurologic manifestations due to small vessel occlusion from tumor cells. Notably, lymphadenopathy is absent in these patients.

Treatment focuses on the underlying malignancy.

CARCINOMATOUS POLYARTHRITIS

Polyarthritis can rarely (<2%) be the presenting manifestation of an occult malignancy and may precede the discovery of the malignancy by several months. Breast, colon, lung, ovarian, and lymphoproliferative malignancies are the most commonly associated cancers. Clinical features suggesting carcinomatous polyarthritis include the explosive onset of a rheumatoid factor–negative, asymmetrical polyarthritis involving predominantly the lower extremities and sparing the hands and wrists in a patient older than age 50 years. Another presentation is remitting seronegative symmetrical synovitis with pitting edema of the hands and feet. Both presentations are associated with profound constitutional symptoms, elevated inflammatory markers, lack of erosions on radiographs, and poor response to glucocorticoids. Polymyalgia rheumatica and late-onset rheumatoid arthritis must be excluded. Treatment of the underlying malignancy results in improvement of the arthritis.

ARTHRITIS ASSOCIATED WITH TREATMENTS FOR MALIGNANT DISEASES

Arthralgias or bone pain is seen in most patients who receive aromatase inhibitors for breast cancer and result in discontinuation of the drug in 20% of patients. Immune checkpoint inhibitors targeting PD-1, PD-L1, or CTLA-4 can cause various immune-related adverse events in 80 to 90% of treated patients.[16] Up to 5% of patients can develop a rheumatologic event, including an inflammatory arthritis resembling rheumatoid arthritis or reactive arthritis. Other manifestations include sicca syndrome, myositis, polymyalgia rheumatica, or vasculitis. Patients may or may not respond to glucocorticoids and/or discontinuation of the cancer immunotherapy, so conventional synthetic and/or biologic disease-modifying drugs may be necessary to control symptoms.

PALMAR FASCIITIS AND ARTHRITIS SYNDROME

Ovarian carcinoma (Chapter 184) is the most common malignancy found in patients (37%) with palmar fasciitis and arthritis. This musculoskeletal manifestation can also be seen in patients with breast, gastric, or pancreatic

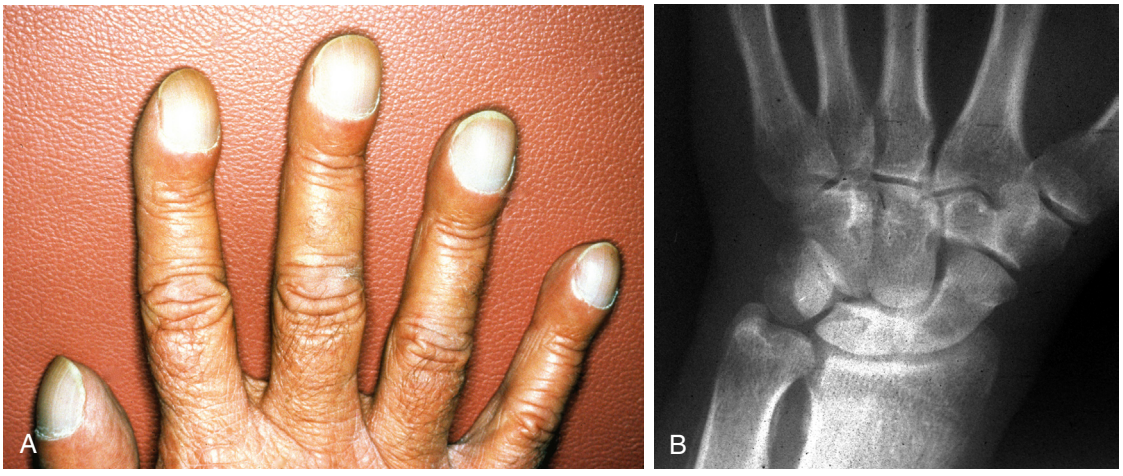

FIGURE 254-1. Hypertrophic osteoarthropathy. A, Severe clubbing of the nails. **B**, Radiograph demonstrating periosteal elevation of the distal radius and ulna.

adenocarcinoma. Patients present with a severe, painful, symmetrical inflammatory polyarthritis of the hands and wrists as well as a nodular fasciitis/tendonitis causing flexion contractures primarily of the fingers and, less commonly, the feet. Patients may have vasomotor instability, thereby causing diagnostic confusion with complex regional pain syndrome or rheumatoid arthritis. This syndrome portends a poor prognosis because it typically manifests after the tumor has metastasized. Response to treatment is poor, although clinical improvement can occur with successful eradication of the underlying tumor.

HEMOCHROMATOSIS

Joint involvement occurs in 40 to 75% of patients with hereditary hemochromatosis (Chapter 196) and may be the presenting symptom (Fig. 254-2).[17] The mechanism whereby iron causes arthritis is unclear, but it may be related to hemosiderin deposits in the synovial membrane and chondrocytes activating degradative enzymes. The metacarpophalangeal (MCP) joints (especially the second and third MCP joints), wrists, knees, hips, shoulders, and ankles are most often involved in a symmetrical pattern. The arthropathy resembles osteoarthritis, with joint swelling resulting from bone enlargement, but it is distinguished clinically by the involvement of atypical joints, such as MCP joints, wrists, and ankles. Radiographs show narrowing of the joint space, subchondral cysts, sclerosis, and hooklike osteophytes at the MCP joints. Chondrocalcinosis is present in up to 50% of patients. Joint involvement is typically asymptomatic, but in some patients it leads to attacks of acute inflammatory synovitis (pseudogout), which may result in the misdiagnosis of rheumatoid arthritis. The prevalence of overt arthritis increases with age, and it may be only minimally symptomatic when the disease arises in other organs. However, articular pain may be the initial presenting complaint (33%). Consequently, all patients (especially White males) presenting with premature osteoarthritis occurring in atypical joints, especially MCP joints and wrists, should be screened for hereditary hemochromatosis. Treatment is symptomatic with NSAIDs (Table 26-4) and, when severe, total joint arthroplasty. Phlebotomy for iron removal does not alter the course of the arthritis. Additional rheumatic manifestations in patients with hemochromatosis include osteoporosis related to hypogonadotropic hypogonadism, osteomalacia related to vitamin D deficiency when liver disease is severe, and an increased susceptibility to *Yersinia* septic arthritis.

MULTICENTRIC RETICULOHISTIOCYTOSIS

Multicentric reticulohistiocytosis (Chapter 155) is a chronic, seronegative, symmetrical, inflammatory polyarthritis most commonly affecting the hands, shoulders, and knees. It may resemble rheumatoid arthritis but can be differentiated by its prominent distal interphalangeal joint synovitis.[18] The disease may also cause a spondylitis with axial involvement (50%). Joint involvement remits and relapses initially, but in 50% of cases it worsens into a severely deforming arthritis mutilans. Firm, nonpruritic, reddish brown or yellow papulonodular lesions ("coral beads") that wax and wane occur around the nail beds and on the face, hands, ears, and other areas predominantly above the waist. Histology of skin lesions reveals characteristic histiocytes and multinucleated giant cells. In 50 to 66% of patients, these diagnostic nodules follow the onset of arthritis by months to years. Additional associations include xanthelasma (33%) and malignancies of various types (25%), which may precede or follow the onset of multicentric reticulohistiocytosis. The disease usually remits spontaneously in 8 to 10 years but often leaves permanent cutaneous and joint damage. No treatment is of proven benefit.

FIGURE 254-2. Arthropathy associated with hemochromatosis. Radiograph demonstrating degenerative changes, with hooklike osteophytes of the second and third metacarpophalangeal joints bilaterally.

SARCOIDOSIS

Joint manifestations, including arthritis, periarthritis, and arthralgias, occur in 4 to 38% of patients with sarcoidosis (Chapter 83).[19] Rheumatic involvement is divided into acute and chronic types. The acute type consists of the triad of arthritis, erythema nodosum, and hilar adenopathy on chest radiographs (Löfgren syndrome), which may be accompanied by fever.[20] Arthritis arises most often in the knees and ankles, and periarticular pain can be severe. Treatment is with NSAIDs, glucocorticoids, or both, and symptoms usually remit spontaneously over several weeks.

The less common chronic type of joint involvement (<5%) in sarcoidosis consists of synovitis that accompanies the slower onset, more chronic, systemic form of sarcoidosis. Polyarthritis, oligoarthritis, or monoarthritis can affect the small or large joints. The arthritis is typically nondestructive, but it can be aggressive. Dactylitis resulting from sarcoid bone and soft tissue involvement can occur (Fig. 254-3). In contrast to the acute type, chronic sarcoid arthropathy is characterized by mildly inflammatory synovial fluid and histologic granulomas on synovial biopsy. Treatment consists of NSAIDs (Table 26-4) and treatment for the sarcoidosis (Chapter 83).

FIGURE 254-3. Sarcoid bone involvement. Punched-out lytic lesions of the middle phalanx, with soft tissue swelling.

Other musculoskeletal manifestations of sarcoidosis include lytic or sclerotic bone lesions (3 to 13%) and symptomatic acute or chronic myopathy (3%). Notably, asymptomatic lesions involving bone and muscle are much more common on MRI and tissue biopsies.

IMMUNOGLOBULIN G4–RELATED DISEASE

Patients with IgG4-related disease are typically men (70 to 75%) older than age 50 years.[21] Patients present with a variety of local and systemic manifestations, some of which can resemble several rheumatic diseases.[22] For example, tumefactive lesions of the salivary glands can mimic Sjögren syndrome. Destructive sinus and middle ear lesions or periorbital masses can suggest granulomatous polyangiitis. Furthermore, patients with IgG4-related disease frequently (40%) have allergic manifestations, including chronic sinusitis and pulmonary symptoms, which may add to the diagnostic confusion with granulomatous polyangiitis.[23] IgG4-related disease can also cause an inflammatory aortitis with aneurysm formation that can be mistaken for giant cell arteritis. A fibrosclerotic presentation in the abdomen can mimic retroperitoneal fibrosis. Other organs that can be involved include the pancreas, biliary tree, kidneys, lymph nodes, meninges, thyroid, breast, prostate, pericardium, and skin. Although up to 70% of patients will have an elevated serum IgG4 level (>1.35 g/L), histopathologic analysis of biopsy specimens is the gold standard for diagnosis. The key pathologic features are a dense lymphoplasmacytic infiltrate organized in a storiform pattern (whorled or cartwheel), obliterative phlebitis, and a mild or moderate eosinophilic infiltrate. The plasma cell infiltrate will show more than 10 IgG4-positive cells per high-power field and a ratio of IgG4 to IgG positive cells that is higher than 40%. Glucocorticoids under expert oversight are effective in most patients. Several medications (azathioprine, mycophenolate mofetil, methotrexate) have been used as steroid-sparing agents to maintain remission. For refractory disease, B-cell depletion therapy with rituximab is effective.

ALKAPTONURIA (OCHRONOSIS)

Although it is an inherited disorder, alkaptonuria (Chapter 189) is usually not diagnosed until the patient presents with progressive premature osteoarthritis as a young adult (before age 30 to 35 years). Deposition of ochronotic pigment onto collagen fibers causes the articular cartilage to become brittle and fragmented. The spine is initially involved, followed by the knees, shoulders, and hips. Small peripheral joints are spared. Nonarticular features include bluish brown discoloration of ear pinna, sclera, and nasal cartilage. The diagnosis is often first suspected when fresh urine turns dark brown or black on standing or with alkalinization. Radiographs show multiple vacuum discs, disc space ossification, and osteoarthritic changes in the spine. The noninflammatory synovial fluid may show tiny shards of pigmented cartilage ("ground pepper"). The diagnosis is confirmed by quantitative measurement of increased homogentisic acid in urine. Testing for a mutation of the *HGD* gene that codes for homogentisate 1,2-dioxygenase can also be performed. There is no effective therapy for alkaptonuria, although the tyrosine metabolism inhibitor nitisinone is currently under investigation. The arthritis is treated symptomatically with analgesics.

FABRY DISEASE

Most patients with hereditary lysosomal storage diseases present and are diagnosed during childhood (Chapter 192). However, female heterozygotes and atypical variants of Fabry disease may have a milder and later-onset phenotype. Fabry disease is an X-linked lipid storage disease caused by a deficiency of lysosomal α-galactosidase A. Males with classical Fabry disease usually develop neuromuscular symptoms in childhood, including painful crises with burning paresthesias of the distal extremities, often accompanied by fever. Abdominal pain is common. However, in female heterozygotes and males with low residual α-galactosidase A levels, disease manifestations may occur for the first time in adulthood. Neuromuscular manifestations can range from painful acroparesthesias to fibromyalgia. Progressive or isolated cardiac, cerebrovascular, and renal disease can develop later. Fabry disease should be suspected in any patient with a paternal family history of early-onset renal failure. Patients should be examined for characteristic ocular stigmata (cornea verticillata) and dermal signs (angiokeratomas). The diagnosis is confirmed in males by determining α-galactosidase A activity in plasma or peripheral leukocytes. In contrast, female carriers must be tested for one of the specific gene mutations. Early diagnosis is important because enzyme replacement therapy can prevent irreversible organ damage.

RELAPSING POLYCHONDRITIS

Relapsing polychondritis (Chapter 239) is an uncommon multisystem disorder characterized by recurrent episodes of inflammation of cartilaginous tissues. Relapsing polychondritis may be part of the VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) syndrome associated with somatic mutations in *UBA1*.[24]

Patients typically present with the sudden onset of pain and erythema involving the cartilage of the external ear, larynx, trachea, or nose. A nonerosive, seronegative polyarthritis or oligoarthritis affecting small, large, or parasternal joints (23 to 47%); ocular inflammation, including episcleritis or scleritis; and audiovestibular disturbances may also be presenting symptoms. The arthritis is typically acute, migratory, and episodic, and it resolves spontaneously over days to weeks. Rarely, it can become chronic. Tenosynovitis is also common.

Treatment of relapsing polychondritis depends on the severity of the presentation and whether major organs are involved (Chapter 239). Late sequelae of relapsing polychondritis include deformity of the pinnae or nose, reduced vision or hearing, tracheal narrowing or collapse, and aortic insufficiency.

CYSTIC FIBROSIS

In up to 10% of patients with cystic fibrosis (Chapter 77), an episodic, nondestructive, inflammatory oligoarthritis develops, most commonly involving the fingers and lower extremity joints. This arthritis is thought to be due to immune complex deposition caused by chronic lung infections. Attacks persist for a few days and may be associated with fever and painful nodular skin lesions and purpura. Other musculoskeletal manifestations include osteoporosis (30 to 75%) and osteomalacia related to malabsorption and, more rarely, hypertrophic osteoarthropathy (5%) and a small vessel vasculitis.

TENOSYNOVIAL GIANT CELL TUMOR: DIFFUSE TYPE

The diffuse type of tenosynovial giant cell tumor (also called diffuse pigmented villonodular synovitis) occurs most commonly in the third and fourth decades of life.[25] Tenosynovial giant cell tumor is a nonmalignant condition commonly due to a translocation between chromosomes 1p13 and 2q35 in which the gene coding for colony-stimulating factor-1 (CSF-1) is fused to the collagen VI alpha-3 gene. Up to 15% of cells overexpress CSF-1. The remaining cells in the tumor are inflammatory cells recruited into the tumor because they contain the receptor for CSF-1.

The disease is characterized by the onset of unilateral pain and swelling of a joint, typically the knee (80%). Unusually, a tendon, bursa, or another joint can be involved. The synovial fluid is typically brown or hemorrhagic, and radiographs may show soft tissue swelling, osteolysis, subchondral cysts, and bone erosions.

Tenosynovial giant cell tumor is best diagnosed by synovial biopsy. Microscopic examination reveals a characteristic histology, including marked

synovial cell hyperplasia and subsynovial invasion by masses of polygonal cells, multinucleated giant cells, and lipid-filled macrophages. Hemosiderin deposits are between and within cells and have a characteristic appearance on MRI, with nodular foci of decreased signal on both T1- and T2-weighted images.

The treatment for pigmented villonodular synovitis is synovectomy with or without postoperative radiotherapy. Pexidartinib targeting the CSF-1/CSF-1R axis may be effective under expert oversight for patients with recurrent, resistant, and inoperable disease.[A1,A2]

255 SURGICAL TREATMENT OF JOINT DISEASES

C. RONALD MACKENZIE AND EDWIN P. SU

EPIDEMIOLOGY

Estimates of the prevalence of arthritis and other rheumatic diseases demonstrate the enormous impact that these conditions have on the U.S. populace and the health care system in general. Over 21% of U.S. adults report physician-diagnosed arthritis. Osteoarthritis (Chapter 241), which is the most prevalent form, affects upward to 31 million U.S. adults. Arthritis is already the leading cause of disability in the United States, yet the number of affected individuals with arthritis and arthritis-attributable limitations in activity is anticipated to approach 67 million by the year 2030. Despite therapeutic advances in the medical treatment of inflammatory arthritic disorders, surgical intervention is eventually required in many patients who suffer from inflammatory arthritis. Furthermore, other than exercise and rehabilitation, surgery is often the only option for degenerative arthritis. The increasing prevalence of arthritis, the desire for higher activity levels, and improvements in surgical techniques have fueled the utilization of orthopedic surgery. By the year 2030, it is predicted that over 500,000 hip replacements and 3 million knee replacements will be performed annually in the United States.

PATHOBIOLOGY

Arthritis results when damage to articular cartilage and accompanying inflammation of the synovium and joint result in the loss of the joint's mechanical properties. Without the protective layer of articular cartilage, stiffness develops. Furthermore, the nociceptive and proprioceptive receptors in the periosteum are activated, thereby leading to pain.

Osteoarthritis (Chapter 241), which is the most common cause of end-stage arthritis, is classified as primary when due to biochemical changes in the cartilage, or secondary if it results from systemic disease affecting the cartilage, joint damage from preexisting inflammatory joint disease, prior infection, previous surgery, congenital or developmental problems, or trauma. Mechanical overload and joint imbalance then lead to further degradation of cartilage. Important adaptive processes, such as subchondral sclerosis and the formation of osteophytes, occur in response to joint overload. Cysts may also form in the subarticular bone. Over time, the osteophytes or bone spurs lead to restricted range of motion (Fig. 255-1).

By contrast, inflammatory arthritis (e.g., rheumatoid arthritis [Chapter 243], psoriatic arthritis, and spondyloarthropathies [Chapter 244]) targets the synovium. The subsequent release of inflammatory mediators leads to destruction of cartilage. In contrast to osteoarthritis, mechanical overload, bone sclerosis, and osteophytes are not seen. Rather, the inflammatory synovitis leads to characteristic loss of cartilage matrix, marginal bony erosions, and osteopenia (Fig. 255-2).

In osteonecrosis (Chapter 229), blood supply to the bone is compromised, thereby leading to necrosis of the bone that supports the articular surface. The most commonly affected joints are the hip, shoulder, and knee. As the condition progresses, the necrotic bone may collapse, thereby leading to the loss of articular integrity and progressive deterioration of cartilage. Other conditions that may lead to joint damage include metabolic disorders (e.g., chondrocalcinosis, gout), tumor (e.g., synovial chondromatosis), and bleeding disorders (e.g., hemophilia).

DECIDING UPON SURGERY

Surgical treatment of joint diseases is focused primarily upon the relief of pain, and patients who are candidates for surgery have daily pain and functional limitations that hinder their quality of life despite physical therapy, pain medications, and intra-articular injections. Secondary objectives are improvement in joint motion and swelling, return to function, and prevention of continued destruction of cartilage.

FIGURE 255-1. Radiograph of an osteoarthritic left hip. Note the asymmetrical joint space narrowing and subchondral sclerosis that are characteristic of a wear-and-tear pattern of joint deterioration.

FIGURE 255-2. Radiograph of a left hip with end-stage inflammatory arthritis. Note the symmetrical pattern of cartilage loss and presence of osteopenia.

synovial cell hyperplasia and subsynovial invasion by masses of polygonal cells, multinucleated giant cells, and lipid-filled macrophages. Hemosiderin deposits are between and within cells and have a characteristic appearance on MRI, with nodular foci of decreased signal on both T1- and T2-weighted images.

The treatment for pigmented villonodular synovitis is synovectomy with or without postoperative radiotherapy. Pexidartinib targeting the CSF-1/CSF-1R axis may be effective under expert oversight for patients with recurrent, resistant, and inoperable disease.[A1,A2]

255 SURGICAL TREATMENT OF JOINT DISEASES

C. RONALD MACKENZIE AND EDWIN P. SU

EPIDEMIOLOGY

Estimates of the prevalence of arthritis and other rheumatic diseases demonstrate the enormous impact that these conditions have on the U.S. populace and the health care system in general. Over 21% of U.S. adults report physician-diagnosed arthritis. Osteoarthritis (Chapter 241), which is the most prevalent form, affects upward to 31 million U.S. adults. Arthritis is already the leading cause of disability in the United States, yet the number of affected individuals with arthritis and arthritis-attributable limitations in activity is anticipated to approach 67 million by the year 2030. Despite therapeutic advances in the medical treatment of inflammatory arthritic disorders, surgical intervention is eventually required in many patients who suffer from inflammatory arthritis. Furthermore, other than exercise and rehabilitation, surgery is often the only option for degenerative arthritis. The increasing prevalence of arthritis, the desire for higher activity levels, and improvements in surgical techniques have fueled the utilization of orthopedic surgery. By the year 2030, it is predicted that over 500,000 hip replacements and 3 million knee replacements will be performed annually in the United States.

PATHOBIOLOGY

Arthritis results when damage to articular cartilage and accompanying inflammation of the synovium and joint result in the loss of the joint's mechanical properties. Without the protective layer of articular cartilage, stiffness develops. Furthermore, the nociceptive and proprioceptive receptors in the periosteum are activated, thereby leading to pain.

Osteoarthritis (Chapter 241), which is the most common cause of end-stage arthritis, is classified as primary when due to biochemical changes in the cartilage, or secondary if it results from systemic disease affecting the cartilage, joint damage from preexisting inflammatory joint disease, prior infection, previous surgery, congenital or developmental problems, or trauma. Mechanical overload and joint imbalance then lead to further degradation of cartilage. Important adaptive processes, such as subchondral sclerosis and the formation of osteophytes, occur in response to joint overload. Cysts may also form in the subarticular bone. Over time, the osteophytes or bone spurs lead to restricted range of motion (Fig. 255-1).

By contrast, inflammatory arthritis (e.g., rheumatoid arthritis [Chapter 243], psoriatic arthritis, and spondyloarthropathies [Chapter 244]) targets the synovium. The subsequent release of inflammatory mediators leads to destruction of cartilage. In contrast to osteoarthritis, mechanical overload, bone sclerosis, and osteophytes are not seen. Rather, the inflammatory synovitis leads to characteristic loss of cartilage matrix, marginal bony erosions, and osteopenia (Fig. 255-2).

In osteonecrosis (Chapter 229), blood supply to the bone is compromised, thereby leading to necrosis of the bone that supports the articular surface. The most commonly affected joints are the hip, shoulder, and knee. As the condition progresses, the necrotic bone may collapse, thereby leading to the loss of articular integrity and progressive deterioration of cartilage. Other conditions that may lead to joint damage include metabolic disorders (e.g., chondrocalcinosis, gout), tumor (e.g., synovial chondromatosis), and bleeding disorders (e.g., hemophilia).

DECIDING UPON SURGERY

Surgical treatment of joint diseases is focused primarily upon the relief of pain, and patients who are candidates for surgery have daily pain and functional limitations that hinder their quality of life despite physical therapy, pain medications, and intra-articular injections. Secondary objectives are improvement in joint motion and swelling, return to function, and prevention of continued destruction of cartilage.

FIGURE 255-1. Radiograph of an osteoarthritic left hip. Note the asymmetrical joint space narrowing and subchondral sclerosis that are characteristic of a wear-and-tear pattern of joint deterioration.

FIGURE 255-2. Radiograph of a left hip with end-stage inflammatory arthritis. Note the symmetrical pattern of cartilage loss and presence of osteopenia.

ABSTRACT

Arthritis is the leading cause of disability in the adult U.S. population. Since such conditions are age-related and often require surgery, their prevalence is expected to increase markedly in the future. Hence, the need for orthopedic surgical intervention is also likely to increase in the years to come. This chapter reviews a wide range of orthopedic procedures, as well as their potential benefit and risks.

KEYWORDS

perioperative medicine
orthopedic surgery
surgical complications

The decision to proceed with surgery reflects the outcome of a partnership among the patient, their primary care physician or rheumatologist, and the orthopedic surgeon. Factors such as the severity of disease, the patient's desired activity level, and the patient's life expectancy are very relevant to decision making. Achieving the necessary decision-making balance may be complicated, especially given the increasing burden of comorbid conditions in the aging patient. Ultimately, the patient and physicians must agree that the possible benefits of surgery outweigh the risks.

Emergent circumstances include hip fracture and infected native or prosthetic joints. Because the patient's general health is at risk in these settings, the medical-surgical team must stabilize the patient as quickly as possible for surgery (Chapter 399).

In the elective setting, joint replacement and spine surgery are the most common procedures. The proportion of surgical procedures performed on an outpatient basis has increased dramatically, and an estimated 50% of total joint replacements in the United States are expected to be performed without hospital admission by 2026. Spinal disease and spine surgery are discussed in detail in Chapter 369.

ANESTHESIA IN THE ORTHOPEDIC PATIENT

General and regional anesthesia (Chapter 400) are commonly used in orthopedic patients. General anesthesia with endotracheal intubation may present a particular danger in patients with rheumatoid arthritis (Chapter 243) or ankylosing spondylitis (Chapter 244) owing to the instability of the cervical spine in the former and rigidity in the latter. Such patients may require fiberoptic intubation. Regional anesthesia with local anesthesia or peripheral nerve blocks[1] using long-acting anesthetics and infusion techniques are often preferred for minor procedures because they provide both excellent intraoperative anesthesia and postoperative pain relief. Epidural/spinal anesthesia can be used for total joint arthroplasty.

ORTHOPEDIC PROCEDURES

OSTEOTOMY

In circumstances in which a structural abnormality around a joint has led to mechanical overload, an osteotomy (bone cutting) may be an option to correct alignment problems. The most common sites for osteotomy are the hip (to treat acetabular dysplasia) and the tibia (to realign the knee). In acetabular dysplasia, the hip socket is excessively shallow, thereby leading to abnormal stresses on the articular cartilage and premature osteoarthritis. An acetabular osteotomy can be performed in patients in whom cartilage still remains. By rotating the pelvic bones, a deeper socket can be formed, thereby reducing stresses on the cartilage and slowing the arthritic process. With tibial osteotomy, the knee joint can be realigned to direct forces away from the region of cartilage damage. Usually a varus (bow-legged) deformity indicates the medial compartment of the knee is excessively worn, and a tibial osteotomy can realign the joint to direct forces to the uninvolved lateral compartment. Typically, osteotomy is considered an option for patients who are younger than age 40 years; beyond this age, the loss of cartilage generally makes total joint arthroplasty the preferred approach.

ARTHROSCOPY

Arthroscopic surgery is performed by inserting a camera and specialized instruments into a joint via small, puncture-type incisions. Arthroscopic surgery is effective in the treatment of intra-articular pathologies such as meniscal tears of the knee, labral tears of the hip, cartilage flaps, small chondral defects, and loose bodies. However, after the articular cartilage is significantly damaged, arthroscopic debridement is usually ineffective unless patients have mechanical symptoms such as locking and clicking.[A1–A4] In some instances, underlying joint arthritis may lead to tears in the meniscus or labrum; if such a tear results in new mechanical symptoms, then arthroscopic surgery may be helpful in selected cases. The benefit of arthroscopic subacromial decompression for shoulder impingement syndrome is variable but appears to be minimal overall.[A5,A6]

In patients who have femoroacetabular impingement (impingement of the femoral neck upon the acetabular rim, typically during flexion and internal rotation), the repetitive contact between the femoral neck and acetabular rim is believed to result in labral tears, cartilage damage, and eventual arthritis.[2] The bones of the femur and acetabulum can be reshaped by an osteochondroplasty, performed as an open or arthroscopic procedure, to provide good symptomatic relief in the short term.[A7] However, the long-term effects, specifically the impact on the future development of arthritis, have yet to be demonstrated for this procedure.

SYNOVECTOMY

Synovectomy is the removal of the synovial lining of the joint, either via an open or arthroscopic approach. In inflammatory conditions such as rheumatoid arthritis (Chapter 243), in which the disease process involves an actively inflamed synovium, synovectomy can relieve pain if sufficient remaining cartilage is still preserved. However, the procedure has not been predictable in terms of regaining joint motion. The most common joints that benefit from synovectomy are the knee and elbow. However, synovectomy should be considered a delaying tactic because the synovium will reappear.

ARTHRODESIS

Arthrodesis, or fusion of a joint, relieves pain by creating a nonmobile joint. The procedure removes the articular surfaces from the joint and immobilizes the bones so that they heal in a solid union. Hip fusion may be performed in young patients to treat the sequelae of slipped capital femoral epiphysis, Legg-Calvé-Perthes disease, postseptic arthritis, or osteonecrosis of the femoral head. Fusion surgery can achieve a painless supportive joint that is capable of bearing heavy loads while avoiding artificial implants. However, creating stiffness at one joint will increase stresses upon the joints above and below the fused joint. Gait mechanics are also altered, thereby requiring more energy for ambulation. Thus, the natural history of a hip fusion is the development of ipsilateral knee arthritis and low back pain after 20 to 25 years, thereby necessitating the conversion of a fused hip to a hip replacement. Although hip arthrodesis is still a viable option in the young arthritic patient, patients' desire for maintaining hip mobility in order to sit and drive have made this procedure largely a treatment of the past.

Fusion of the knee joint is generally considered a salvage procedure, mainly used in situations in which replacement is not possible (e.g., lack of muscle function or persistent infection). In addition to the lack of motion that may make it difficult to sit or climb stairs, knee fusion cannot be converted to total knee replacement.

Ankle fusion is still commonly performed as the treatment of choice of tibiotalar arthritis. Because the results of ankle replacement may not be durable, fusing the ankle is an equally good[A8] method of creating a pain-free joint. Furthermore, the ability of the knee and subtalar joints to compensate for a stiff ankle has made this procedure more tolerable.

TOTAL JOINT ARTHROPLASTY

Joint arthroplasty refers to the re-creation of congruent joint surfaces, typically with artificial parts. In certain patients and in non–load-bearing joints such as the elbow, interpositional arthroplasty can be performed by placing a tissue graft between the arthritic surfaces. For weight-bearing joints (e.g., the hip, knee) as well as the shoulder, however, metal and plastic materials produce the most durable results, so the procedures are commonly called total hip, knee, and shoulder replacements. In such procedures, the articular surfaces are replaced by shaped materials designed to recreate the joint kinematics.

In general, once the articular cartilage is completely worn or destroyed on both sides of the joint, arthroplasty becomes the most predictable option to relieve pain. Because a total joint arthroplasty involves artificial, moving components, the replaced joints are subject to the same wear and tear as native joints. Thus, they have a finite lifespan, which is dependent upon a patient's weight and activity level, as well as the implant materials. After total joint arthroplasty, it is advisable to reduce stresses upon the joint by weight loss and avoidance of impact activities. Walking, cycling, and gliding-type activities are permitted but, in general, running and jumping should not be performed. Subsequent revisions of joint replacements can be difficult and less durable, so it is wise to defer joint arthroplasty until there are no other options. Emerging data support a decreased revision rate when total hip replacements and total knee replacements are performed with computer navigation assistance. A growing trend in the United States is to perform total joint arthroplasty as an outpatient procedure in a surgical center, with selected patients able to be discharged to home on the same day of the operation.[3]

Hip

Total hip replacement, which is the treatment of choice for end-stage arthritis,[4] is the removal of the arthritic femoral head at the level of the femoral neck and removal of enough acetabular bone to place a prosthetic socket. The femoral implant is inserted into the intramedullary canal and anchored with bone-ingrowth techniques or bone cement. The surgical approach can be anterior, supercapsular,[A9] or posterior,[5] with the latter generally requiring more recovery time but associated with fewer major complications. The weight-bearing materials for the hip can be metal-on-polyethylene,

ceramic-on-polyethylene, or ceramic-on-ceramic, depending on the patient's age and activity level, as well as the surgeon's preference (Fig. 255-3). Using modern implant materials and surgical techniques, implant survival rates are 90 to 95% at 20 years, but longevity varies depending upon factors such as the patient's weight and activity.[6]

Hip resurfacing is quickly increasing as an alternative to total hip replacement in younger, more active patients.[7] The primary benefit is the preservation of proximal femoral bone in the event that future (revision) surgery is necessary. Rather than removing the femoral head and a portion of the femoral neck, as in total hip replacement, the bone is sculpted to accept a metal resurfacing cap (like a tooth), thereby preserving an additional 4 to 5 cm of bone (Fig. 255-4). The acetabulum is prepared to accept a metal socket, thereby creating a metal-on-metal joint. The preservation of the proximal femoral bone raises an additional risk of failure (i.e., femoral neck fracture below the resurfacing implant), which is estimated to occur in 1% of cases. Although hip resurfacing has no defined age limits, the best candidates have been males under the age of 55, likely because the bone quality in this demographic group is the strongest. In this age group, hip resurfacing has a 90 to 95% joint survival rate, free of revision, which is an equivalent outcome to total hip replacement at the same time point. However, concerns regarding longevity, a greater short-term failure rate than total hip replacement, poorer results in women, and metal ion release have led to questions concerning the superiority of the procedure.

FIGURE 255-3. Radiograph of a total hip replacement consisting of uncemented acetabular and femoral components. The articulating material are a metal ball and polyethylene liner.

FIGURE 255-4. Radiograph of a patient with a right total hip replacement and a left hip resurfacing. The total hip replacement consists of a longer stem placed into the medullary canal of the femur. The hip resurfacing implant preserves the proximal femoral bone.

For hip fractures, accelerated surgery within 6 hours of diagnosis is no better than standard care.[A10] In patients who are independently ambulating before suffering from displaced femoral neck fractures, total hip arthroplasty is perhaps slightly better than hemiarthroplasty in terms of future function and quality of life.[A11] If hemiarthroplasty is chosen, a cemented fixation is preferred.[8]

Knee

Total knee replacement[9] involves the removal of the arthritic surfaces of the tibia and femur, followed by their replacement with a metal femoral implant and a metal and/or polyethylene tibial component (Fig. 255-5). The recovery from total knee replacement is more difficult than after total hip replacement because of greater postoperative pain and the emphasis on regaining motion. Nonetheless, pain relief and function are usually excellent once recovery is complete.[A12] Implant survival is 90 to 95% at 15 years, depending upon patient factors.

However, only about 70 to 85% of patients may be satisfied with their pain relief following the procedure, likely because of the difficulty in reproducing the complex ligamentous interactions of the native knee joint with metal and plastic components. This problem has led to a growing use of unicompartmental or partial knee replacement in appropriate candidates, in an attempt to preserve the native ligamentous structures. In unicompartmental knee replacement, which is a bone-preserving implant for the knee, only one of the three knee compartments is replaced with a prosthetic device (see Fig. 255-6), so candidates must have arthritis limited to a single compartment. Because surgical trauma and dissection are significantly reduced compared with total knee replacement, recovery tends to be less painful and quicker. Furthermore, because the native ligaments of the knee are preserved, patients have a greater range of motion and satisfaction level compared with total knee replacement. However, the failure rate at 10 to 15 years is higher for unicompartmental knee replacement because of the possibility of developing arthritic changes elsewhere in the joint.

Shoulder

Although less commonly performed than hip and knee replacement, total shoulder replacement is an excellent pain-relieving procedure for glenohumeral arthritis.[10] Total shoulder replacement uses a stemmed humeral implant with a metal ball and metal and/or polyethylene glenoid socket. Total shoulder replacement requires an extensive rehabilitation protocol to regain range of motion and strength, but 95% of patients have pain-free use of the shoulder by 1 year after surgery.

Elbow, Ankle and Wrist

The elbow,[11] ankle, and wrist are less frequently replaced joints. With the exception of the rheumatoid wrist, these joints are less commonly afflicted by chronic arthritis. Further, the smaller bones making up these joints also translate to a diminished surface area for implant fixation, thereby reducing the durability of the surgical procedures. Although total joint arthroplasty can be successful at

FIGURE 255-5. Radiograph of a total knee replacement. The components are metal, with a polyethylene insert between the tibial and femoral components.

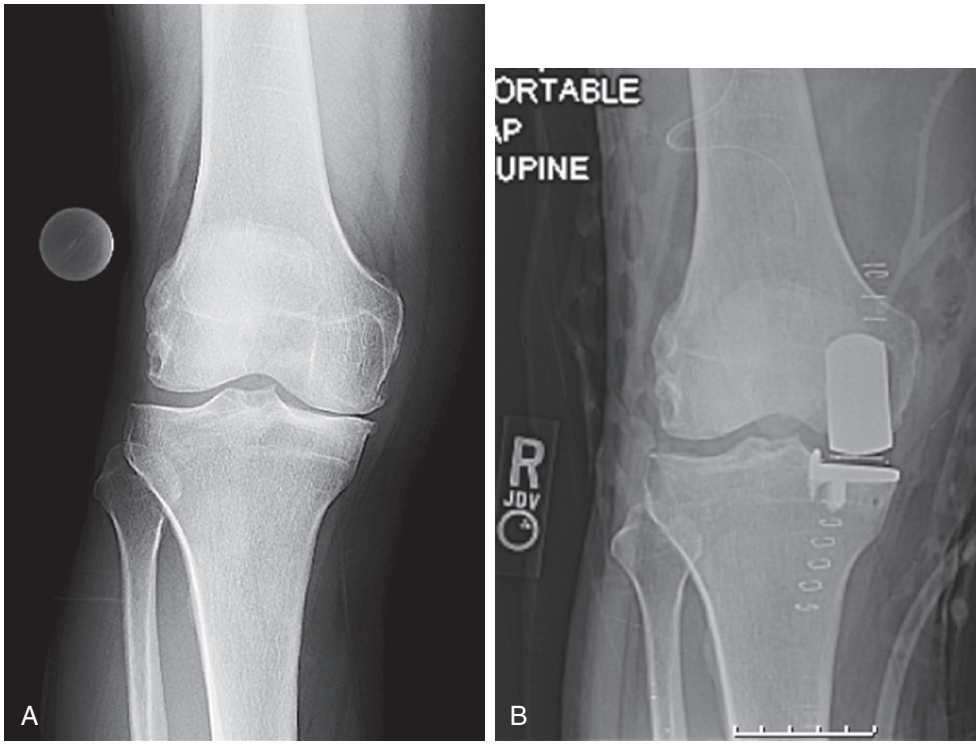

FIGURE 255-6. A, Radiograph of a knee with arthritis limited to the medial compartment. B, A medial unicompartmental knee replacement.

relieving pain in the short-term, 10-year results do not approach that of total hip or knee replacement. Synovectomy remains an effective surgical option in selected patients with inflammatory arthritis of the elbow, ankle, or wrist.

Spine

Surgery for diseases of the spine is discussed in Chapter 369.

SURGICAL COMPLICATIONS

POSTOPERATIVE PAIN

Options for the control of postoperative pain include the traditional intravenous or intramuscular routes of narcotic medications (Table 26-6), the use of spinal or epidural analgesia, and the local infiltration of anesthetics into the surgical site. In patients without contraindications (Chapter 26), parenterally administered nonsteroidal anti-inflammatory agents (NSAIDs; Table 26-4) are also useful to reduce narcotic requirements after major surgery. The direct administration of local mixtures of medications, including long-acting anesthetics and anti-inflammatory drugs, has become more popular because of the ease of use and excellent efficacy, particularly around the hip and knee joints. For both total hip replacement and total knee replacement, dexamethasone (4 to 8 mg perioperatively) can reduce postoperative nausea and vomiting, reduce pain, and facilitate earlier discharge from the hospital.[A13,A14] Nerve blocks have largely replaced patient-controlled epidural anesthesia in the outpatient setting. Pain relief facilitates postoperative physical therapy, which is important for the restoration of range of motion.

INFECTION

Periprosthetic joint infection remains a rare but devastating complication, especially after total joint arthroplasty. Because of the ability of microbiologic organisms to form biofilms on the surface of the prosthetic implant, deep joint infections involving a prosthetic joint cannot be eradicated without surgical intervention.

The gold standard in treating chronic prosthetic joint infection has been a two-stage surgical procedure that includes debridement of infected tissues and removal of the implant during the first stage, with subsequent reimplantation of a new implant constituting the second stage (Chapter 251).[12] Typically, an antibiotic-impregnated cement spacer is inserted during the first stage as a temporary implant to deliver high-dose antibiotics (see Chapter 251) locally; it also serves to facilitate some movement at the joint, thereby making eventual surgical reimplantation easier. After the first stage, intravenous antibiotics are given for 6 weeks, followed by a drug holiday to allow for reassessment of possible persistent infection. If the surgically treated joint appears to be persistently infected, the first stage is repeated. Once a treated joint is clear of infection, the goal is to proceed with the second stage, which is reimplantation of the joint without further need for antibiotics. The typical time frame between the first and second stages is 3 to 6 months.

Another option is one-stage removal and reimplantation of the prosthesis, with intravenous antibiotics for 6 weeks (see Chapter 251), followed by extended oral antibiotics. This approach is best used in an immunocompetent host without soft-tissue compromise (such as a draining sinus) and when the microbiologic organism is particularly sensitive to antibiotics. The duration of the antibiotic suppression can vary but in general is for at least 6 months after the surgical procedure.

Debridement and implant retention is another option in acute infections of less than 4 weeks' duration. In this procedure, any implant parts that can be easily removed and replaced, such as the polyethylene liner, are exchanged for new parts. Intravenous antibiotics are typically given for 6 weeks and followed by lifelong chronic oral antibiotic suppression afterward.

In view of the morbid consequences of prosthetic joint infection, efforts to prevent and detect any infectious processes preoperatively and postoperatively are of utmost importance. The skin and urinary tract are sites of specific concern. In addition, dental consultation may be appropriate in patients with poor oral hygiene and dentition. In patients with a history of infection, particularly prior methicillin-resistant *Staphylococcus aureus,* preoperative surveillance cultures with topical treatment for positive results (Chapter 267) are often performed.

Prophylactic antibiotic therapy for total joint arthroplasty patients should begin less than 2 hours before surgery and continue for 24 hours. A common protocol involves cefazolin (1 g every 8 hours for three doses) or, in penicillin-allergic patients, vancomycin (1 g every 12 hours for two doses).

PERIPHERAL NERVE INJURIES

Peripheral nerve injuries, which arise more often after upper and lower extremity surgery, generally result from excessive traction on the nerve or, alternatively, as a consequence of nerve compression as a result of prolonged positioning of the extremity during surgery or in a cast. Early detection and intervention are critical. Patients with chronic neurologic conditions, such as neuropathies in the setting of diabetes or spinal stenosis, are at increased risk of nerve injury.

VENOUS THROMBOEMBOLISM

After orthopedic surgery, a complicated balance exists between a possible life-threatening pulmonary embolus and the potential for postoperative bleeding. A shorter intraoperative time and the use of epidural or regional anesthesia may

reduce the risk of deep venous thrombosis. Other intraoperative interventions, such as hypotensive anesthesia and intraoperative heparin administration, further reduce thrombogenesis. Mechanical methods to reduce the risk of thromboembolism include compression stockings, various pneumatic devices, and foot flexion-extension exercises.

The mainstays of prevention however, are early mobilization combined with prophylactic anticoagulation. Aspirin is often used for low-risk patients after elective total hip and knee arthroplasty, and it is as safe and effective as low-molecular-weight heparin after a fracture of an extremity or of the pelvis or acetabulum.[A15] For higher risk patients,[13] regimens include direct-acting oral anticoagulants (Table 70-6)[A16] and low-molecular-weight heparin (Tables 68-7 and 70-3), with data indicating that rivaroxaban is more effective than enoxaparin to prevent venous thromboembolism in orthopedic patients undergoing lower limb surgery.[A17] Such anticoagulants are often used in combination with various mechanical compression devices. Emerging data suggest that inhibition of factor XI may be equally effective and safer for prophylaxis (Chapter 68).[A18]

FAT EMBOLISM

Fat embolization (Chapter 68), a well-described complication of skeletal trauma, may also occur after procedures involving instrumentation of the femoral medullary canal. The embolization of some amount of fat is believed to occur in almost all patients who sustain hip or femoral fractures. Among patients undergoing joint replacement surgery (particularly simultaneous bilateral procedures), 1 to 3% develop fat embolism syndrome,[14] which is discussed in detail in Chapter 68.

PERIOPERATIVE ARTHRITIS MEDICATION

The scheduling of joint surgery often must consider the ongoing use of a variety of rheumatologic medications. Guidelines are available to determine which should be continued or discontinued (E-Table 255-1).[15]

E-TABLE 255-1 MEDICATIONS FOR THE PERIOPERATIVE MANAGEMENT OF PATIENTS UNDERGOING ELECTIVE TOTAL HIP OR TOTAL KNEE ARTHROPLASTY*

	DOSING INTERVAL	RECOMMENDED TIMING OF SURGERY SINCE LAST MEDICATION DOSE
MEDICATIONS TO CONTINUE THROUGH SURGERY		
DMARDs: continue these medications through surgery (all patients)		
Methotrexate	Weekly	Anytime
Sulfasalazine	Once or twice daily	Anytime
Hydroxychloroquine	Once or twice daily	Anytime
Leflunomide (Arava)	Daily	Anytime
Doxycycline	Daily	Anytime
Apremilast (Otezla)	Twice daily†	Anytime†
Severe SLE-specific medications: continue these medications in the perioperative period in consultation with the treating rheumatologist‡		
Mycophenolate mofetil	Twice daily	Anytime
Azathioprine	Daily or twice daily	Anytime
Cyclosporine	Twice daily	Anytime
Tacrolimus	Twice daily (IV and PO)	Anytime
Rituximab (Rituxan)	IV every 4-6 months†	Month 4-6†
Belimumab SQ (Benlysta)	Weekly†	Anytime†
Belimumab IV (Benlysta)	Monthly†	Week 4†
Anifrolumab (Saphnelo)§	IV every 4 weeks†	Week 4†
Voclosporin (Lupkynis)§	Twice daily†	Continue†
MEDICATIONS TO WITHHOLD PRIOR TO SURGERY¶		
Biologics: withhold these medications through surgery		
Infliximab (Remicade)	Every 4, 6, or 8 weeks	Week 5, 7, or 9
Adalimumab (Humira)	Every 2 weeks	Week 3
Etanercept (Enbrel)	Every week	Week 2
Abatacept (Orencia)	Monthly (IV) or weekly (SQ)	Week 5; week 2
Certolizumab (Cimzia)	Every 2 or 4 weeks	Week 3 or 5
Rituximab (Rituxan)	2 doses 2 weeks apart every 4-6 months	Month 7
Tocilizumab (Actemra)	Every week (SQ) or every 4 weeks (IV)	Week 2; week 5
Anakinra (Kineret)	Daily	Day 2
IL-17 secukinumab (Cosentyx)	Every 4 weeks	Week 5
Ustekinumab (Stelara)	Every 12 weeks	Week 13
Ixekizumab (Taltz)§	Every 4 weeks†	Week 5†
IL-23 guselkumab (Tremfya)§	Every 8 weeks†	Week 9†
JAK inhibitors: withhold this medication 3 days before surgery#		
Tofacitinib (Xeljanz)	Daily or twice daily†	Day 4†
Baricitinib (Olumiant)§	Daily†	Day 4†
Upadacitinib (Rinvoq)§	Daily†	Day 4†
Not severe SLE: withhold these medications 1 week before surgery		
Mycophenolate mofetil	Twice daily	1 week after last dose†
Azathioprine	Daily or twice daily	1 week after last dose
Cyclosporine	Twice daily	1 week after last dose†
Tacrolimus	Twice daily (IV and PO)	1 week after last dose†
Rituximab (Rituxan)	Every 4-6 months	Month 7
Belimumab IV (Benlysta)	Monthly†	Week 5†
Belimumab SQ (Benlysta)	Weekly†	Week 2†

*Dosing intervals obtained from prescribing information provided online by pharmaceutical companies. Adapted from the 2017 American College of Rheumatology/American Association of Hip and Knee Surgeons guideline.

†Recommendation that has changed since 2017.

‡Severe SLE indicates organ-threatening disease.

§Drug added for 2022 update.

¶For patients with rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, or all SLE for whom antirheumatic therapy was withheld before undergoing total joint arthroplasty, antirheumatic therapy should be restarted once the wound shows evidence of healing; any sutures/staples are out; there is no significant swelling, erythema, or drainage; and there is no ongoing nonsurgical site infection, which is typically ~14 days.

#Recommendation pertains to infection risk and does not account for risk of cardiac events or venous thromboembolism.

DMARDs = disease-modifying antirheumatic drugs; IL-17 = interleukin-17; IV = intravenous; PO = by mouth; SLE = systemic lupus erythematosus; SQ = subcutaneous.

256 INTRODUCTION TO MICROBIAL DISEASE: PATHOPHYSIOLOGY AND DIAGNOSTICS

ROBIN PATEL AND VICTORIA J. FRASER

Infectious diseases have profoundly influenced the human genome and the course of human history. As of early 2023, severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapters 335 to 337) infection has caused nearly 7 million deaths worldwide. Beginning in the 1980s, acquired immunodeficiency syndrome (AIDS; Chapters 353 to 359) disrupted the social fabric of many countries, especially in Africa, and distressed health care systems in the United States and other parts of the world. Approximately 38 million people worldwide are currently infected with human immunodeficiency virus (HIV), and since 1981, approximately 37 million people have died (about 700,000 in the United States alone). Deaths due to HIV/AIDS peaked at 1.9 million a year in 2005 and fell to 650,000 by 2021. Even before the SARS-CoV-2 pandemic, about 2.5 million people died annually worldwide from lower respiratory tract infections. Globally, an estimated 241 million new malaria infections occur annually, with 627,000 associated deaths. Each year, over 1.5 million people die worldwide from diarrheal diseases.

Serious infectious diseases may be associated with more morbidity over time due to rising global temperatures (Chapter 17).[1] The World Health Organization (WHO) predicts that climate change will result in 250,000 additional deaths per year between 2030 and 2050. Of this increase, about 110,000 deaths will be related to malaria (Chapter 316) and diarrheal disease owing to expansion of insect vector populations and increased coastal flooding, respectively.

Infection can be defined as the multiplication of microbes (from viruses to multicellular parasites) in blood and/or host tissues. The host may or may not experience symptoms. For example, HIV infection may not cause any overt signs or symptoms of illness for years. The definition of infection also includes multiplication of microbes on the surface or in the lumen of the host, thereby causing signs and symptoms of illness or disease. For example, toxin-producing strains of *Escherichia coli* (Chapter 280) may multiply in the gut and cause a diarrheal illness without invading tissues. Microbes can cause diseases without actually coming in contact with the host by virtue of toxin production. *Clostridium botulinum* (Chapter 271) may grow in certain improperly processed foods, producing a toxin that can be lethal on ingestion. A relatively trivial infection, caused by *Clostridium tetani* (Chapter 271) in a small puncture wound, can cause devastating illness because of a toxin released from the organism growing in tissues. It has now become apparent that multiple virulence factors of microorganisms can be carried in tandem on so-called pathogenicity islands of the genome (the "virulome").

Humans live in a virtual sea of microorganisms, with all body surfaces having indigenous bacterial microbiota (Chapter 257). An individual's native microbiota constitute as many cells as their human cells. Our normal microbiota protects us from infection. Alterations of gut microbiota increase susceptibility to infection by pathogens such as *Salmonella enterica* (Chapter 284) and *Clostridioides difficile* (Chapter 271). Bacteria that constitute normal microbiota microorganisms are thought to exert a protective effect by several mechanisms: using nutrients and occupying an ecologic niche, thus competing with pathogens; producing antibacterial substances that inhibit growth of pathogens; and inducing host immunity that is cross-reactive against pathogens. These mechanisms appear to be oversimplistic, however. For example, gut colonization with *Bacteroides fragilis* expressing an immunodominant bacterial polysaccharide causes dendritic cell activation and induction of a T_H1-mediated response, thereby leading to a splenic response characterized by normal numbers of $CD4^+$ T cells, lymphoid architecture, and systemic lymphocytic expansion. Thus, a single bacterial molecule in our gut can improve immunologic fitness, and a healthy, diverse microbiome is vital to proper immune system function.

Only a small proportion of microbial species can be considered primary pathogens, and even among these species, a relatively small number of clones cause disease. For example, epidemic meningococcal meningitis and meningococcemia (Chapter 274) are due to a small number of clones of *Neisseria meningitidis*, and the worldwide explosion of penicillin-resistant *Streptococcus pneumoniae* (Chapter 268) can be traced to a few clones originating in South Africa and Spain. This observation supports the concept that pathogenic organisms are highly adapted to the pathogenic state and have developed characteristics that enable them to be transmitted, to attach to surfaces, to invade tissue, to avoid host defenses, and thus to cause disease. In contrast, opportunistic pathogens, which may be harmless members of normal microbiota of healthy persons, can act as virulent invaders in patients who have severe defects in host defense mechanisms. However, opportunistic infection is not simply an exploitation of a weakened host by relatively avirulent pathogens. *Pseudomonas aeruginosa* (Chapter 282), for example, recognizes immunologic perturbations in the host and reacts by expressing virulence factors.

Pathogenic organisms may be acquired by several routes. For example, direct contact has been implicated in acquisition of staphylococcal disease (Chapter 267). Aerosols and droplets spread SARS-CoV-2 (Chapters 335 and 336). Contaminated water is the usual vehicle in *Giardia* infection (Chapter 322) and typhoid fever (Chapter 284). Food-borne illnesses may be caused by extracellular toxins produced by *Clostridium perfringens* (Chapter 271) and *Staphylococcus aureus* (Chapter 267). Blood and blood products may be vectors for transmitting hepatitis B and C viruses (Chapter 134) as well as HIV (Chapter 353). Sexual transmission is also important for these agents and for a variety of other pathogens, including *Treponema pallidum* (syphilis; Chapter 295), *Neisseria gonorrhoeae* (gonorrhea; Chapter 275), and *Chlamydia trachomatis* (urethritis; Chapter 294). The fetus may be infected in utero; infection may be devastating if the agent is rubella virus (Chapter 339), cytomegalovirus (Chapter 347), or parvovirus B19 (Chapter 342). Arthropod vectors are also important, as illustrated by mosquitoes for malaria (Chapter 316) and dengue (Chapter 352); ticks for Lyme disease (Chapter 296), anaplasmosis, and ehrlichiosis; and lice for typhus (Chapter 302).

Pathogens are able to cause disease because of a finely tuned array of adaptations, including the ability to attach to appropriate cells, often mediated by specialized structures, such as pili. Microbes such as *Shigella* species (Chapter 285) have the ability to invade cells and cause damage. Toxins may act at a distance or affect only infected cells. Pathogens can thwart host defenses by a variety of ingenious maneuvers. The antiphagocytic coat of the pneumococcus (Chapter 268) is an example. Organisms may change their surface antigen display at a rapid rate to outmaneuver the host immune system. Examples include influenza virus (Chapter 332) and trypanosomes (Chapters 317 and 318). Certain pathogens (e.g., *Toxoplasma gondii*; Chapter 320) can inhibit the respiratory burst of phagocytes, and others (e.g., *Streptococcus pyogenes*; Chapter 269) can destroy phagocytic cells that have engulfed them. The environment plays an important role in infection, both in transmission and in the host's ability to combat the invader. The humidity and temperature of air may affect infectivity of airborne pathogens. The sanitary state of food and water, woefully lacking in many areas of the world, is an important factor in the acquisition of enteric pathogens. It is also likely that micronutrient deficiency contributes to the invasion and multiplication of certain pathogens.

Host reaction to infection may result in illness. For example, previous infection with *Campylobacter jejuni* (Chapter 279) is responsible for about 40% of cases of Guillain-Barré syndrome (Chapter 388). The mechanism is thought to be production of antibodies against *C. jejuni* lipopolysaccharides that cross-react with gangliosides in peripheral nerves. Similarly, much of the damage resulting from meningitis is due to the host's response to invading bacterial pathogens.

With some exceptions, infectious diseases are treatable and curable, so it is important to make an accurate diagnosis and to institute appropriate therapy promptly. In acute infections such as pneumonia (Chapter 85), meningitis (Chapter 381), or sepsis (Chapter 94), rapid institution of therapy can be lifesaving. In such cases, treatment (based on history, physical examination, and epidemiology of illness in the community) should be started even if a definitive diagnosis has not been confirmed. Antimicrobial therapy for the presumptive causative agent(s) can later be re-evaluated as more definitive diagnostic information becomes available. Rapid diagnostic techniques, including Gram stains, antigen detection, or nucleic acid amplification testing, often can be helpful.

EMERGING INFECTIONS

Recent examples of emerging infections with a major impact on public health in the United States and internationally include HIV, community-associated methicillin-resistant *S. aureus* (MRSA), a hypervirulent strain of *C. difficile*, 2009 H1N1 influenza, multidrug-resistant gram-negative bacteria (e.g., carbapenem-resistant Enterobacterales), *Candida auris*, Kratom-associated salmonellosis, and SARS-CoV-2. Examples of recent localized outbreaks include but are not limited to cholera (Yemen), diphtheria (Bangladesh), H7N9 influenza

ABSTRACT

Infections are a major cause of morbidity and mortality worldwide. Only a fraction of microorganisms are recognized as primary human pathogens as a result of their having abilities to attach to and/or enter human cells, produce toxins, and/or evade the host immune system. By comparison, commensal organisms in the human microbiome are essential for human health.

Pathogenic organisms may be acquired by a variety of means, including via direct contact, aerosols, droplets, contaminated food or water, sexual contact, blood, tissue products, organ transplantation, or arthropod vectors, such as mosquitoes or ticks. Emerging infections, including most recently severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), can spread quickly in the global era.

If appropriately diagnosed, infections are often treatable, with many being curable. The diagnostic evaluation for infectious diseases requires knowledge of the appropriate test(s) to order, as well as their correct interpretation. Testing includes not only stains and cultures but also the detection of antibodies and antigens, as well as the increasing use of nucleic acid amplification tests, such as the polymerase chain reaction, and sequencing.

(China), listeriosis (South Africa), plague (Madagascar), yellow fever (Brazil), Zika (the Americas), chikungunya (the Americas), and Ebola (West Africa).

More than 400 new, emerging, or reemerging infectious diseases have been described over the past 70 years, approximately 60% of which are zoonoses associated with geographic "hot spots." The emergence of these infections is driven largely by ecologic, socioeconomic, and environmental factors.

GENOMICS

The exact genomic sequence of thousands of microbes relevant to humans has been determined, and careful analysis will yield important information about the pathogenesis of infection.[2] For example, genome sequencing of *S. pyogenes* (Chapter 269), collected over time with relevant robust clinical information, has detected the acquisition of new determinants that are responsible for increased virulence and that result in toxic shock syndrome, necrotizing fasciitis, or both.

GENETIC SUSCEPTIBILITY AND RESPONSE TO INFECTION

Genomics can provide new and significant information relevant to an individual's response to an infectious disease. For example, an overvigorous response, with generation of tumor necrosis factor-α, may accentuate development of cerebral complications in *falciparum* malaria. Analysis of single-nucleotide polymorphisms of the human genome could lead to enhanced understanding of two fundamental issues in infectious diseases: why invasive, overt disease develops in only a small fraction of individuals challenged with a given microbe and why infections are more severe in some people than in others. Variants in genes that encode molecules that mediate attachment, pathogen recognition, inflammatory cytokine response, and innate and adaptive immunity are being identified at an astonishing rate. For example, inherited deficiencies of C3, alternative pathway components (factor D, properdin, factor H, and factor I), and terminal complement pathway components (C5 through C9) are associated with an increased incidence of invasive meningococcal and gonococcal infection.

INNATE IMMUNITY

The identification of pattern recognition receptors (e.g., toll-like receptors and nucleotide oligomerization domain–like receptors) that recognize pathogen-associated molecular patterns, as well as endogenous substances reflecting tissue injury (e.g., alarmins), has revolutionized understanding of the early host response to infection. Agonists or antagonists of toll-like receptors have already entered clinical trials as adjuvant therapies or to improve the immunogenicity of vaccines. Antimicrobial peptides (e.g., defensins, cathecidins, histatins, galectins) also have an important role in the early response to infectious disorders and can also be leveraged as diagnostics. As an example, alpha-defensin testing of synovial fluid is used to diagnose infections associated with joint prostheses.

ANTIMICROBIAL RESISTANCE

The development of new antibacterial agents has slowed despite the burgeoning problem of antimicrobial resistance. Drug-resistant bacteria can spread easily in health care facilities and through international travel. Urgent threats include carbapenem-resistant *Acinetobacter* species (Chapter 283), *N. gonorrhoeae* (Chapter 275), *C. auris* (Chapter 310), *C. difficile* (Chapter 271), and carbapenem-resistant Enterobacterales (Chapter 281), whereas serious threats include drug-resistant *Campylobacter* species (Chapter 279), *Candida* species (Chapter 310), *Salmonella* (Chapter 284) and *Shigella* species (Chapter 285), *S. pneumoniae* (Chapter 268), tuberculosis (Chapter 299), extended-spectrum beta-lactamase–producing Enterobacterales (Chapter 281), MRSA (Chapter 267), vancomycin-resistant enterococci (Chapter 270), and multidrug-resistant *P. aeruginosa* (Chapter 282).[3]

Sometimes the trade-off between antimicrobial success and antibiotic resistance is challenging. For example, mass azithromycin use can reduce childhood mortality in sub-Saharan Africa but at the expense of a seven- to eight-fold increase in macrolide resistance.[A1]

THE ROLE OF INFECTIOUS AGENTS IN CHRONIC DISEASES

Hepatitis B and C viruses (Chapter 135), human papillomavirus (Chapter 344), and *Helicobacter pylori* (Chapter 125) are among the infectious agents that can cause human cancers. Furthermore, colorectal cancers often harbor bacteria.

Many so-called idiopathic diseases also may have an infectious basis, as was discovered for Whipple disease (Chapter 305) in about 1990. Conditions for which there is some evidence (but not conclusive proof) of an infectious basis include diabetes, atherosclerosis, acute leukemia, collagen vascular diseases, and inflammatory bowel disease. Detection of uncultivatable microorganisms by newer techniques, such as 16S ribosomal RNA gene or shotgun metagenomic analysis, may uncover agents responsible for diseases hitherto considered noninfectious or suggest a role in conditions that are considered infectious but in which the pathogen or pathogens are controversial.

DIAGNOSIS

Three questions need to be answered with microbiologic testing. The first is whether a patient's illness is microbial in nature. The second is to define the organism(s) causing the illness. The third is to determine how the patient should be treated. If treatment is not directly evident from the nature of the organism detected, susceptibility testing is performed, typically on an organism recovered in culture.

Diagnostic testing for infectious diseases requires appropriate ordering and interpretation of results.[4] As clinical microbiology tests become increasingly complex, consultation with infectious diseases specialists or clinical microbiologists is recommended in challenging situations. Infections can be caused by hundreds of species of microorganisms, ranging from bacteria to viruses, fungi, protozoa, parasites, and even algae. Simply detecting an organism does not mean that it is causing the patient's illness, because of the possibility of it being contaminating or colonizing microbiota or from a prior infection. Testing methods, which include direct detection using visualization (often with specific stains), culture (which may be specialized, depending on the organism type), and molecular, proteomic, metabolomic, and immunologic methods, are ever-expanding and may vary from laboratory to laboratory. Nucleic acid amplification tests, which amplify microbial nucleic acid (DNA and/or RNA, depending on the organism targeted) are increasingly used in clinical practice. The most common nucleic acid amplification test in clinical use is the polymerase chain reaction (PCR), but many other technologies are available.[5] With PCR, a specific segment of DNA is amplified using a pair of primers (Fig. 256-1) (forward and reverse) in a reaction that includes the bases needed to synthesize DNA (deoxynucleotide triphosphates) and a heat-stable DNA polymerase. The reaction itself involves serial cycling of temperatures to anneal the primers, synthesize DNA between them (via an enzyme called DNA polymerase), and then convert DNA from double- to single-stranded DNA to allow the reaction to recur. The upshot is that at the end of temperature cycling, the targeted DNA segment, if present, is exponentially amplified; the amplified DNA is detected using one of a variety of strategies, including fluorescently labeled probes that hybridize to amplified DNA during the course of the PCR reaction—so-called real-time PCR. The cycle number at which this signal is detected, referred to as the cycle threshold value, is a general indicator of the amount of target nucleic acid present, with lower cycle threshold values correlating with the presence of higher amounts of target DNA. Measurement of host response to infection, including traditional serologic testing, interferon-γ release assays, and measurement of host transcriptional or proteomic responses, may be applied. Organisms isolated in culture are typically identified using the proteomic technology matrix-assisted laser desorption ionization time-of-flight mass spectrometry, which enables accurate identification of a myriad of bacterial and fungal isolates in minutes.

Collection of Specimens

The quality of microbiology results depends not just on testing in the laboratory but also on proper selection, collection, and transportation of specimens for testing. Specimens for microbiology testing are ideally collected, especially for culture-based tests, before administration of antimicrobial agents. It is important for those collecting specimens to ensure proper specimen collection; specimens of poor quality may be rejected by the laboratory but only if the laboratory can identify them as such (e.g., a putative sputum specimen that is really just oropharyngeal secretions). Certain types of tests are inappropriate for some specimen types (e.g., anaerobic cultures on sputum). Swabs hold minute volumes and are recommended in limited situations (e.g., throat swabs to diagnose *S. pyogenes* pharyngitis and nasal or nasopharyngeal swabs to diagnose SARS-CoV-2 infection). Flocked swabs, which efficiently release their contents, are increasingly used. If tissues or fluids can be collected, they are preferred over swabs.

Blood Cultures

Blood cultures, typically incubated for 5 days on modern continuous-monitoring blood culture instruments, allow recovery of most cultivable bacteria and most *Candida* species. Growth usually occurs within the first day of incubation; rapid tests for identification and susceptibility testing can be performed on the

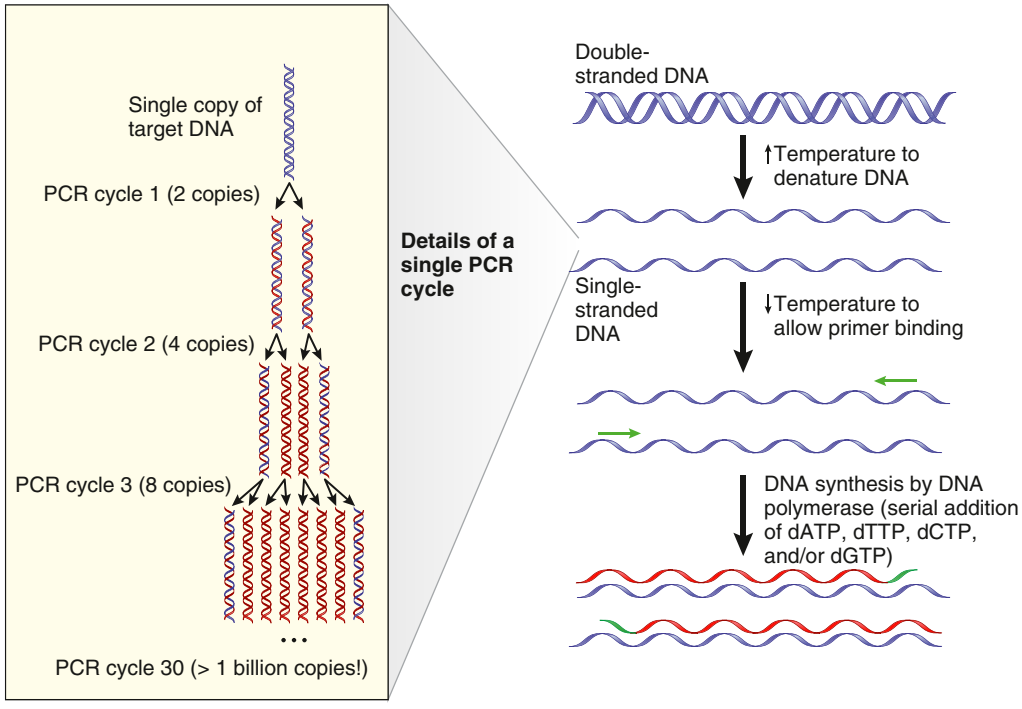

FIGURE 256-1. Polymerase chain reaction (PCR). dATP = deoxyadenosine triphosphate; dCTP = deoxycytidine triphosphate; dGTP = deoxyguanosine triphosphate; dTTP = thymidine triphosphate.

contents of positive blood cultures to provide expedited results.[6] Mycobacteria and dimorphic fungi ideally require specialized blood cultures and longer incubation times.

Collection of an optimal volume of blood and drawing blood cultures before administration of antibiotics are quality practices for conventional blood cultures. For adults, two culture sets or draws, each consisting of 20 to 30 mL of blood, should be obtained from separate venipuncture sites after each site has been disinfected (e.g., with chlorhexidine or 2% iodine tincture) and then inoculated into at least one aerobic and one anaerobic bottle per set. There is no need to space blood culture draws over time. Single-draw blood cultures are discouraged. Clinicians are notified when a blood culture becomes positive, but it may not be immediately clear whether the identified organism represents a pathogen or a contaminant. Contaminated blood cultures are common, with acceptable contamination rates as high as 3%, and can cause clinical confusion. Contamination can be recognized when blood cultures yield organisms such as coagulase-negative *Staphylococcus* species or *Corynebacterium* species from a single set. To minimize contamination, a dedicated phlebotomy team is ideal. An approach to prevent contamination is to aspirate blood initially into a separate tube or vessel and then to obtain cultures with subsequent blood aspiration.[A2]

Although catheter-drawn blood cultures are generally discouraged, a catheter-drawn blood culture set alongside a simultaneously collected peripherally drawn blood culture set may be helpful to diagnose catheter-associated bacteremia. If both grow the same organism and the blood culture collected from the intravascular catheter becomes positive more than 2 hours before the culture drawn peripherally (differential time to positivity), there is a high likelihood of catheter-related bloodstream infection. In the case of multi-lumen catheters being assessed for catheter-associated bacteremia, consideration may be given to collection of blood through each lumen, along with a peripheral draw.

To diagnose infective endocarditis (Chapter 61), routine blood cultures are suggested; if negative, *Bartonella* and Q fever serology should be considered. Histopathology, stains, and molecular diagnostics (e.g., 16S ribosomal RNA gene PCR/sequencing, *Tropheryma whipplei* nucleic acid amplification testing) may be applied to resected valves if the microbiologic diagnosis has not been established by other means.

Cerebrospinal Fluid

Cerebrospinal fluid can be useful to diagnose meningitis (Chapter 381) and some cases of encephalitis (Chapter 383) (e.g., herpes simplex virus, enterovirus). Sufficient sample should be collected for all desired tests; it is helpful to collect extra fluid to be stored in the laboratory in case add-on tests are later desired so as to avoid the need for a second lumbar puncture. Typically, three or four cerebrospinal fluid aliquots are collected in separate tubes. The first has the greatest potential for contamination and should not be used for microbiology studies. Gram stain prepared after cytocentrifugation of cerebrospinal fluid and bacterial culture should be performed (along with conventional blood cultures and measurement of opening pressure), with cell count and differential, glucose, and protein, for diagnosis of bacterial meningitis. Cryptococcal antigen testing is indicated if cryptococcal meningitis (Chapter 309) is possible. Nucleic acid amplification tests of cerebrospinal fluid are best for diagnosis of enteroviral and herpes meningitis/encephalitis. Pneumococcal antigen and nucleic acid amplification tests for varicella zoster virus should be considered in acute meningitis/encephalitis. A multiplex nucleic acid amplification test panel[7] is especially useful for detecting viruses if individual nucleic acid amplification tests are not available and in antibiotic-treated patients, but it is not a replacement for culture. For the diagnosis of tuberculous meningitis (Chapter 381),[8] acid-fast bacillus smear and culture of large volumes (≥5 mL) of cerebrospinal fluid, as well as nucleic acid amplification testing, are recommended. For more complicated cases, neurology and/or infectious diseases consultation is suggested, because the differential diagnosis is broad and the evaluation may be complex.

Respiratory Specimen Testing

S. pyogenes pharyngitis (Chapters 269 and 397) is diagnosed by collecting a swab of the throat and tonsils (avoiding the teeth, gums, and cheeks) and testing it using culture, a rapid antigen test, or a nucleic acid amplification test. Rapid antigen tests have limited sensitivity for *S. pyogenes*, especially in children, and negative results should ideally be confirmed by culture or a molecular assay. Nucleic acid amplification tests are ideally used to detect respiratory viruses[9] and *Bordetella pertussis* (Chapter 289).

For outpatient community-acquired pneumonia (Chapter 85),[10] specific testing is generally considered optional. For patients who are admitted to the hospital, however, pretreatment blood cultures, Gram stain and culture of sputum, and, if disease is severe, urine antigen tests for *Legionella pneumophila* and *S. pneumoniae* are recommended. Nucleic acid amplification tests are preferred for pneumonia caused by *Mycoplasma pneumoniae* (Chapter 293) or *Chlamydia pneumoniae* (Chapter 294) and for legionellosis (Chapter 290). For diagnosis of hospital-acquired and ventilator-associated pneumonia, induced sputum can be tested on nonintubated patients and endotracheal aspirates or bronchoalveolar lavage fluid on intubated patients, using Gram stain and culture; multiplex nucleic acid amplification test panels are available.

For diagnosis of pulmonary tuberculosis (Chapter 299), expectorated sputum (or induced sputum or bronchoscopically obtained specimens) should be submitted for acid-fast bacillus smear (three specimens), mycobacterial

culture (three specimens), and *M. tuberculosis* nucleic acid amplification testing (one specimen). In acid-fast bacillus smear–positive patients, a negative *M. tuberculosis* nucleic acid amplification test makes a diagnosis of pulmonary tuberculosis unlikely. In acid-fast bacillus smear–negative patients with an intermediate or higher level of suspicion for pulmonary tuberculosis, a negative *M. tuberculosis* nucleic acid amplification test cannot exclude pulmonary tuberculosis. Some nucleic acid amplification tests for *M. tuberculosis* both detect the organism and provide rapid molecular drug susceptibility testing (e.g., rifampin with or without isoniazid).

Stool

Community-acquired diarrhea often resolves in less than a week in the absence of treatment, so laboratory testing is not generally needed, unless the patient has fever, bloody diarrhea, dysentery, severe abdominal pain, or dehydration or is hospitalized or immunocompromised (Chapter 262). For travel-related diarrhea (Chapter 265) or community-acquired diarrhea persisting a week or longer, laboratory testing can be useful. The specimen of choice is diarrheal stool. Bacterial, parasitic, and viral gastroenteritis pathogens may be detected with commercial multiplex nucleic acid amplification tests, which can yield results in as little as 1 hour.[11] Routine stool cultures typically evaluate for *Salmonella*, *Shigella*, and *Campylobacter* species and should also include evaluation for Shiga toxin–producing *E. coli* using a nucleic acid amplification test or antigen assay. *Vibrio* and *Yersinia* culture may be separate, specific requests because they are performed using specialized media. Infection with *Giardia* species (Chapter 322), *Cryptosporidium* species (Chapter 321), or *Cyclospora cayetanensis* may present similarly to bacterial gastroenteritis, and these organisms are ideally identified using antigen detection or nucleic acid amplification tests. Likewise, norovirus (Chapter 350) and other viral etiologies of gastroenteritis are ideally detected by nucleic acid amplification tests; rotavirus (Chapter 350) can alternatively be detected using an antigen detection assay.

C. difficile–associated diarrhea is often associated with antecedent antibiotic use or hospitalization, although community-acquired cases occur; in suspected cases of *C. difficile*–associated diarrhea, specific testing is recommended by testing diarrheal stool using either a glutamate dehydrogenase antigen detection assay plus toxin A and B detection using an antigen detection assay (with or without arbitration by a nucleic acid amplification test for toxin-associated genes) or by performing a nucleic acid amplification test with toxin testing. Alternatively, a nucleic acid amplification test can be used alone, provided the patient being tested is likely to have *C. difficile*–associated diarrhea.

Urine

Differentiation of asymptomatic bacteriuria, cystitis, and pyelonephritis requires clinical evaluation because Gram stain and culture findings may be similar for the three (Chapter 263). Specimens submitted for bacterial urine culture should be collected in a way that minimizes contamination from perineal microbiota. The use of urine transport media, refrigeration after collection, and specimen collection with straight "in-and-out" catheterization decrease the growth of small numbers of contaminating organisms, which can result in false-positive results. Urine specimens from patients who have indwelling urinary catheters for even a few hours frequently have colonizing microbiota owing to biofilm formation on catheter surfaces, so positive urine cultures may not represent a true urinary tract infection.

For diagnosis of acute bacterial prostatitis (Chapter 114), the classic four-specimen approach, involving collection of the first 10-mL void, a midstream specimen, expressed prostate secretions, and a 10-mL post–prostate-massage urine may be used. The test is considered positive if there is a 10-fold higher bacterial count in the expressed prostate secretions than the midstream urine. A two-specimen version, involving only midstream urine and expressed prostate secretions, is an alternative.

Antimicrobial Susceptibility Testing

Antimicrobial susceptibility testing should be performed to guide ultimate narrow-spectrum antimicrobial agents even in situations in which broader empiric therapy must be started before culture and susceptibility results are known. The "gold standard" method for susceptibility testing is phenotypic susceptibility testing, which involves growing the organism with and without specific antimicrobial concentrations and then comparing results. The traditional measurement of susceptibility is the minimum inhibitory concentration (MIC), which is the lowest concentration of the antimicrobial agent that inhibits growth of the organism. To measure the MIC, the organism is grown in various concentrations of an antimicrobial agent. Use of the term *susceptible* implies that the MIC is at a concentration attainable in blood or other appropriate body fluid using usually recommended doses. *Resistant*, which is the converse of susceptible, implies that the MIC is not exceeded by normally attainable levels. In some situations, the MIC lies between susceptible and resistant levels, and the result may be reported as *intermediate* or *susceptible–dose dependent*, the latter to indicate that the antimicrobial agent may still be used but at increased doses. Urine levels of some antimicrobial agents (e.g., nitrofurantoin) may be so high as to enable their use to treat urinary tract infections even in the face of high MICs.

257 THE HUMAN MICROBIOME

VINCENT B. YOUNG

The human microbiome has received considerable attention as a previously underappreciated factor in human health and disease.[1–4] Alterations in the microbiome are associated with several clinical conditions, and restoration of a normal intestinal microbiome can be beneficial in selected situations.

DEFINITIONS

The so-called normal flora of microbes that live in and on the human body are part of the normal human microbiome. Although most attention has been paid to bacteria, this term can also encompass the Archaea, yeast, and viruses. The term *microbiota* refers to the microbes themselves, whereas the term *microbiome* refers to a specific community of microbes (i.e., microbiota) and the specific environment that they inhabit. This distinction is important because the microbiome encompasses the microbiota and also the environment they inhabit. This environment is shaped not only by the microbes but also by the host and the external environment. For example, the intestinal microbiome is composed of the microbes that inhabit this organ as well as the intestinal contents, which includes compounds derived from food as well as from the human host, such as digestive enzymes, mucin, and bile acids.

STRUCTURE AND FUNCTION RELATIONSHIPS OF THE MICROBIOME

The function of microbes in a specific environment can be ascertained by examining not only the community members but also determining the complete metabolic environment that these microbes inhabit. This metabolic environment is defined not only by the microbes but also by the host.[5] A specific example is the metabolism of bile acids found in the intestinal tract. Synthesized in the liver and excreted in bile in the form of bile salts conjugated to the amino acids taurine and glycine, these primary conjugated bile salts are further metabolized by members of the intestinal microbiota, which can remove these conjugated amino acids and further alter the chemical structure through enzymatic activities such as dehydroxylation. Secondary bile acids, which result from the microbe-mediated conversion of primary bile acids, have different chemical properties and thus influence host physiology in a differential manner. Bile acid receptors are differentially stimulated by various secondary bile acids, so metabolism of bile acids by the microbiota will have a direct influence on host physiology.

culture (three specimens), and *M. tuberculosis* nucleic acid amplification testing (one specimen). In acid-fast bacillus smear–positive patients, a negative *M. tuberculosis* nucleic acid amplification test makes a diagnosis of pulmonary tuberculosis unlikely. In acid-fast bacillus smear–negative patients with an intermediate or higher level of suspicion for pulmonary tuberculosis, a negative *M. tuberculosis* nucleic acid amplification test cannot exclude pulmonary tuberculosis. Some nucleic acid amplification tests for *M. tuberculosis* both detect the organism and provide rapid molecular drug susceptibility testing (e.g., rifampin with or without isoniazid).

Stool

Community-acquired diarrhea often resolves in less than a week in the absence of treatment, so laboratory testing is not generally needed, unless the patient has fever, bloody diarrhea, dysentery, severe abdominal pain, or dehydration or is hospitalized or immunocompromised (Chapter 262). For travel-related diarrhea (Chapter 265) or community-acquired diarrhea persisting a week or longer, laboratory testing can be useful. The specimen of choice is diarrheal stool. Bacterial, parasitic, and viral gastroenteritis pathogens may be detected with commercial multiplex nucleic acid amplification tests, which can yield results in as little as 1 hour.[11] Routine stool cultures typically evaluate for *Salmonella*, *Shigella*, and *Campylobacter* species and should also include evaluation for Shiga toxin–producing *E. coli* using a nucleic acid amplification test or antigen assay. *Vibrio* and *Yersinia* culture may be separate, specific requests because they are performed using specialized media. Infection with *Giardia* species (Chapter 322), *Cryptosporidium* species (Chapter 321), or *Cyclospora cayetanensis* may present similarly to bacterial gastroenteritis, and these organisms are ideally identified using antigen detection or nucleic acid amplification tests. Likewise, norovirus (Chapter 350) and other viral etiologies of gastroenteritis are ideally detected by nucleic acid amplification tests; rotavirus (Chapter 350) can alternatively be detected using an antigen detection assay.

C. difficile–associated diarrhea is often associated with antecedent antibiotic use or hospitalization, although community-acquired cases occur; in suspected cases of *C. difficile*–associated diarrhea, specific testing is recommended by testing diarrheal stool using either a glutamate dehydrogenase antigen detection assay plus toxin A and B detection using an antigen detection assay (with or without arbitration by a nucleic acid amplification test for toxin-associated genes) or by performing a nucleic acid amplification test with toxin testing. Alternatively, a nucleic acid amplification test can be used alone, provided the patient being tested is likely to have *C. difficile*–associated diarrhea.

Urine

257 THE HUMAN MICROBIOME

VINCENT B. YOUNG

The human microbiome has received considerable attention as a previously underappreciated factor in human health and disease.[1–4] Alterations in the microbiome are associated with several clinical conditions, and restoration of a normal intestinal microbiome can be beneficial in selected situations.

DEFINITIONS

The so-called normal flora of microbes that live in and on the human body are part of the normal human microbiome. Although most attention has been paid to bacteria, this term can also encompass the Archaea, yeast, and viruses. The term *microbiota* refers to the microbes themselves, whereas the term *microbiome* refers to a specific community of microbes (i.e., microbiota) and the specific environment that they inhabit. This distinction is important because the microbiome encompasses the microbiota and also the environment they inhabit. This environment is shaped not only by the microbes but also by the host and the external environment. For example, the intestinal microbiome is composed of the microbes that inhabit this organ as well as the intestinal contents, which includes compounds derived from food as well as from the human host, such as digestive enzymes, mucin, and bile acids.

STRUCTURE AND FUNCTION RELATIONSHIPS OF THE MICROBIOME

The function of microbes in a specific environment can be ascertained by examining not only the community members but also determining the complete metabolic environment that these microbes inhabit. This metabolic environment is defined not only by the microbes but also by the host.[5] A specific example is the metabolism of bile acids found in the intestinal tract. Synthesized in the liver and excreted in bile in the form of bile salts conjugated to the amino acids taurine and glycine, these primary conjugated bile salts are further metabolized by members of the intestinal microbiota, which can remove these conjugated amino acids and further alter the chemical structure through enzymatic activities such as dehydroxylation. Secondary bile acids, which result from the microbe-mediated conversion of primary bile acids, have different chemical properties and thus influence host physiology in a differential manner. Bile acid receptors are differentially stimulated by various secondary bile acids, so metabolism of bile acids by the microbiota will have a direct influence on host physiology.

ABSTRACT

The human microbiome has received considerable attention as a previously underappreciated factor in human health and disease. The microbiome plays an important role in nutrition and conditions such as inflammatory bowel diseases, intestinal and respiratory infections, and graft-versus-host disease. Restoration of a normal intestinal microbiome has beneficial effects in severe malnutrition and for the treatment of *Clostridioides difficile*.

STUDYING THE MICROBIOME

The microbiome is usually analyzed by nucleic acid sequencing–based techniques and mass spectrometry (E-Fig. 257-1). In some cases the information is limited to the structure (anatomy) of a microbial community in terms of the species composition and relative abundance of the microbes that are present. Functional data (physiology) can be gained by assaying metabolic potential or direct measurement of functional output in terms of gene expression and a catalog of the metabolites that are present in the microbiome. A remaining question that often lingers in these studies is whether specific changes that are associated with a specific health state is positive or merely reflects the altered environment that is created by the presence of that state. Ongoing research is endeavoring to determine whether alterations in the microbiome truly have a causal role for associated disease.

ESTABLISHMENT OF THE MICROBIOME

The birth mode can have at least a short-term effect on the composition of the microbiota of a newborn. Neonates who undergo vaginal birth have a distinct microbiome shortly after birth compared with children born by cesarean delivery. These distinctions resolve as the child grows older. What is unknown is whether these differences in early colonization have long-lasting effects on the health of the child. It is possible that these differences in initial microbiomes may underlie the known epidemiologic associations between cesarean birth and conditions such as asthma and allergies.

In addition to birth mode, a number of postnatal factors such as use of antibiotics, breast-feeding, diet, and host genetics are thought to affect the developing microbiota of the child (E-Fig. 257-2). After an "adult-like" microbiota is established, the microbiota varies by body region (Fig. 257-1) and among individuals,[6] but the sum total of the microbial genes shows much less variation (E-Fig. 257-3). The interpretation is that although the specific composition of the normal, healthy microbiota may vary from person to person, conserved functions are present in a healthy community.

ALTERATION OF THE MICROBIOME

Given the apparent conservation of microbiome function in healthy individuals, an extensive literature has evaluated alterations in the microbiota. However, a causal role by which the altered microbiota leads to disease has been demonstrated only for a few conditions.[7]

The microbiota possesses a wealth of metabolic potential for a wide range of catabolic and bioconversion activities (Fig. 257-2). Dietary substances such as carbohydrates and proteins can be metabolized by the indigenous

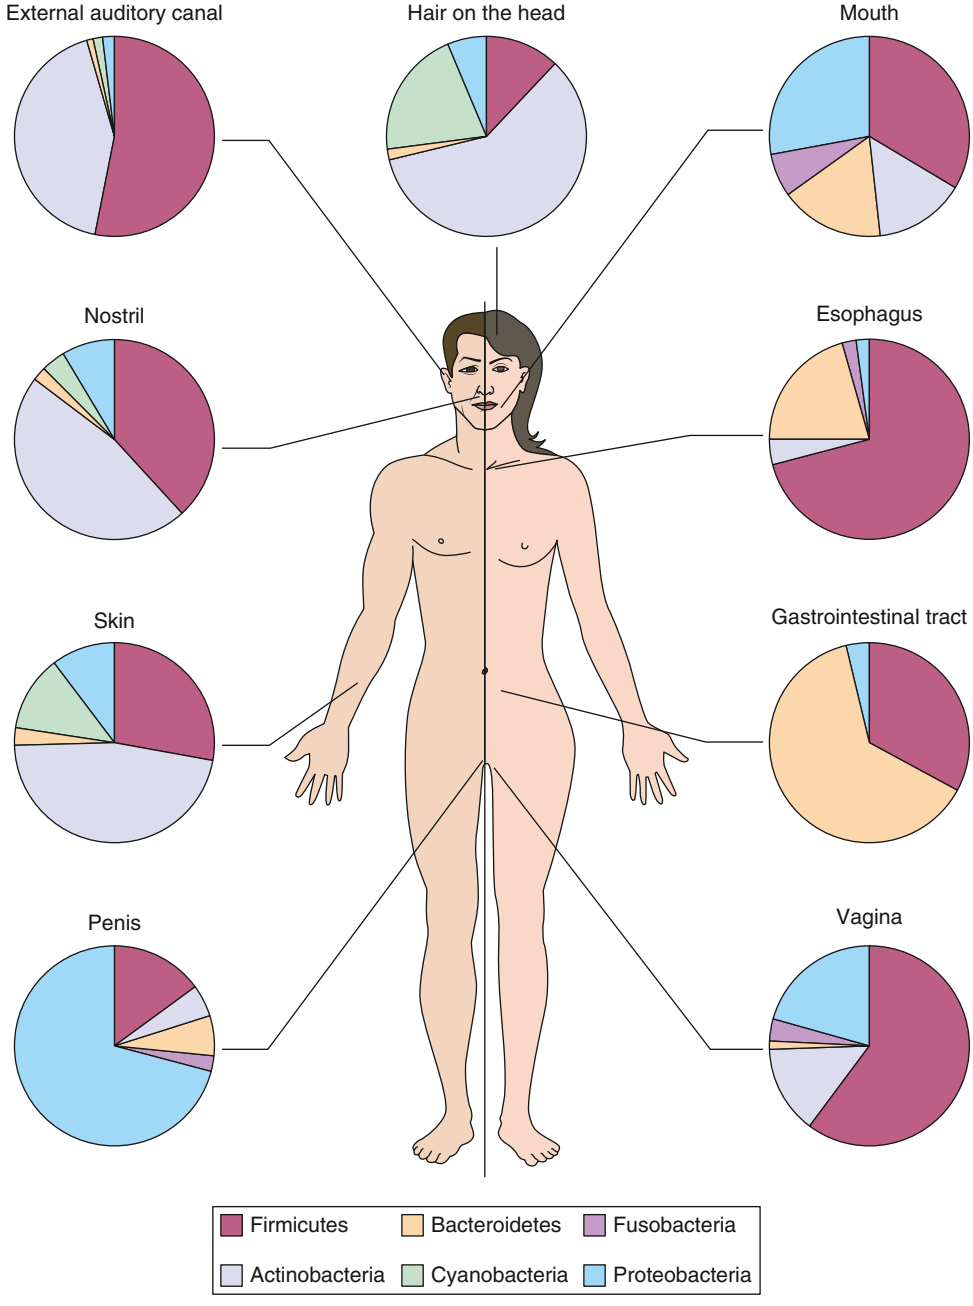

FIGURE 257-1. The relative abundances of the six dominant bacterial phyla in different body sites. Data are taken from multiple surveys of the microbiota. (From Spor A, Koren O, Ley R. Unravelling the effects of the environment and host genotype on the gut microbiome. *Nat Rev Microbiol*. 2011;9:279-290.)

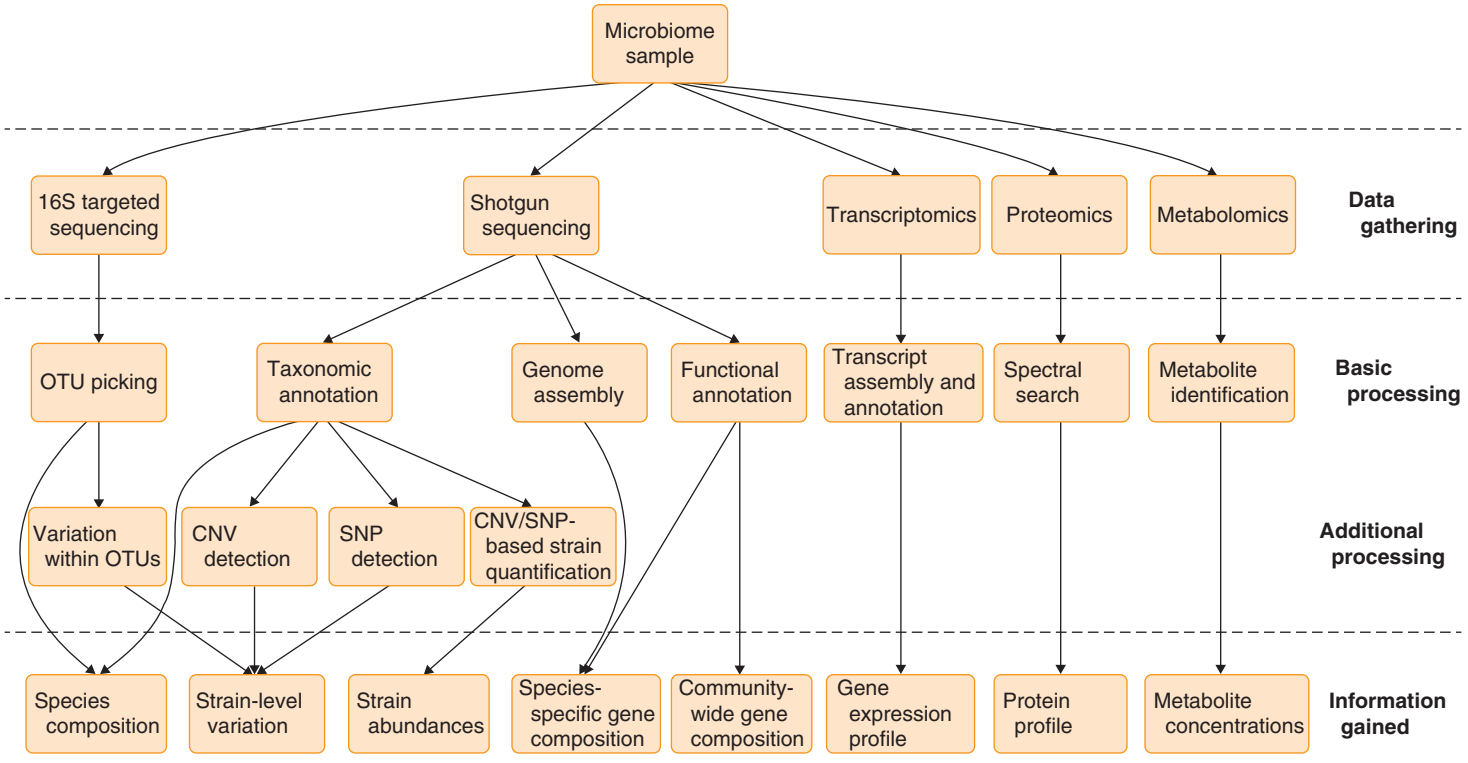
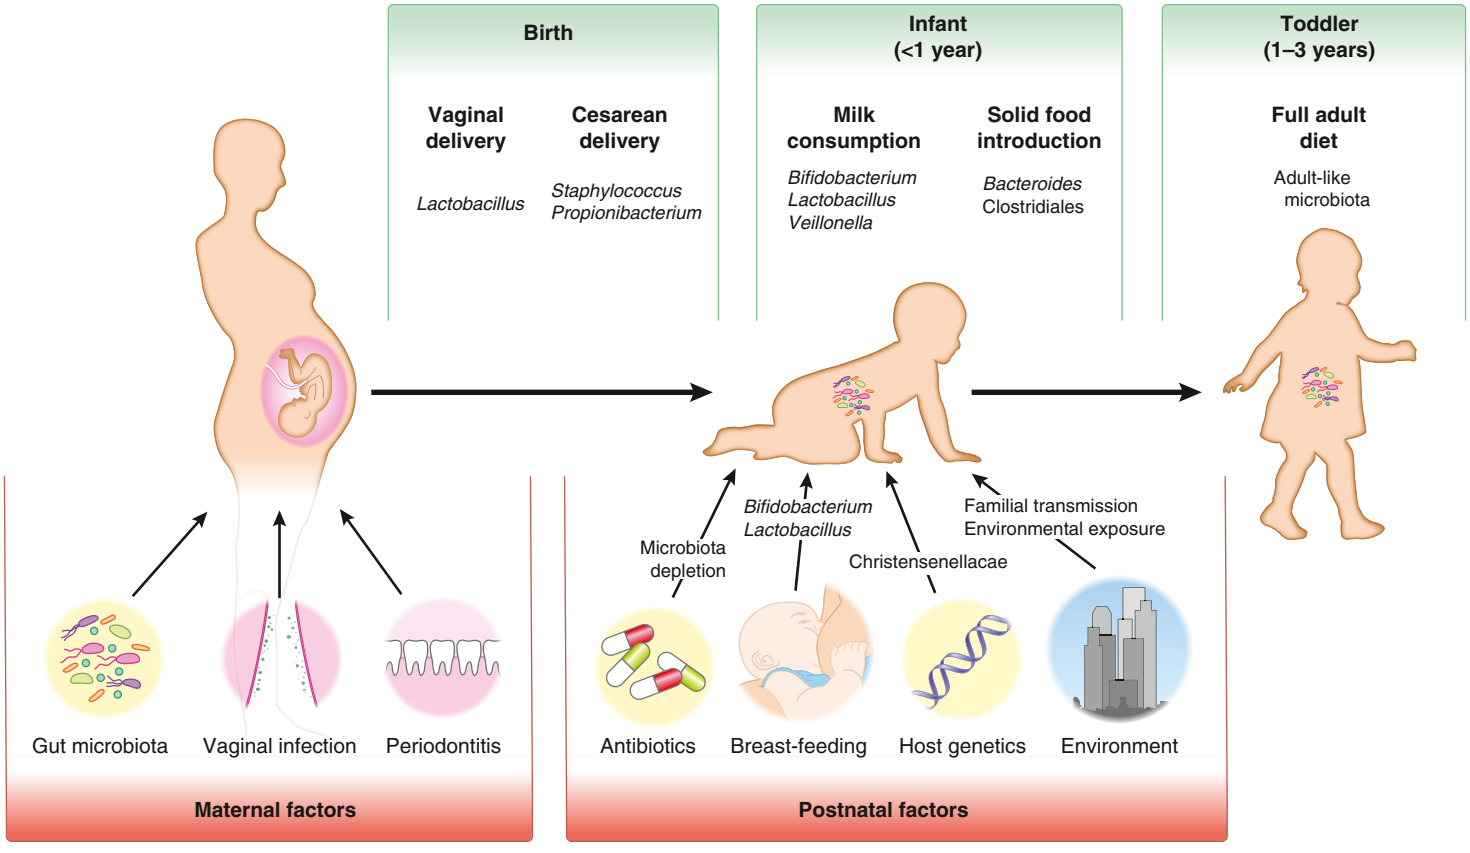
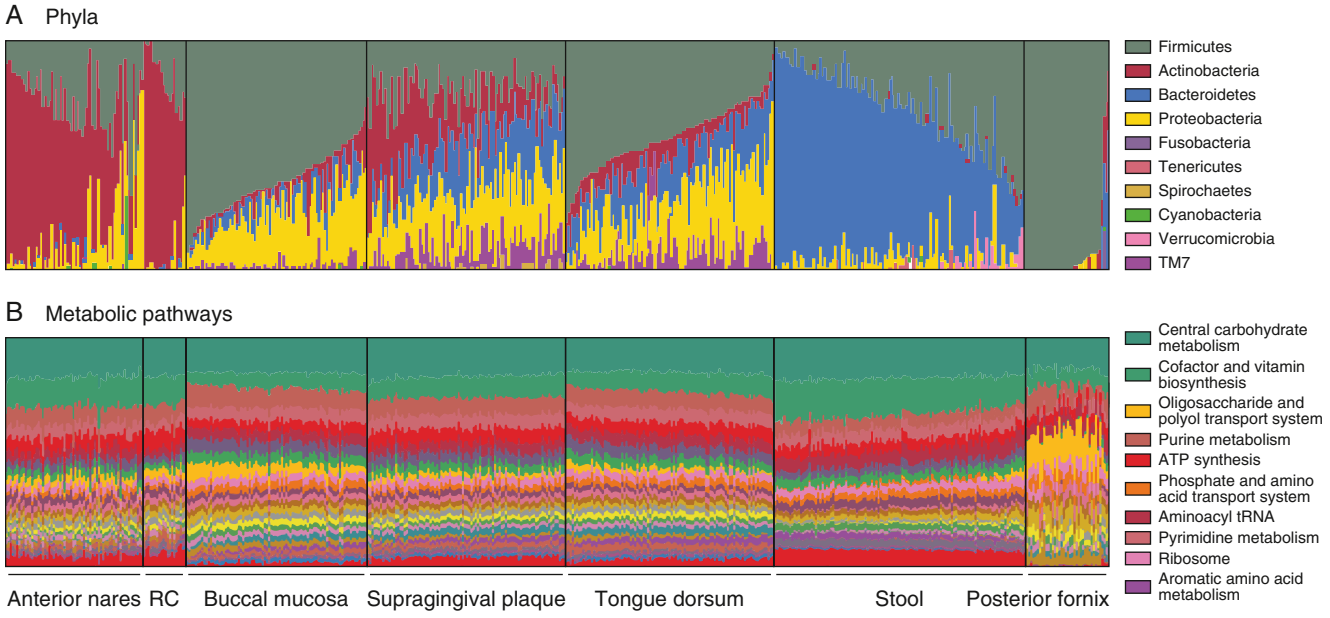


E-FIGURE 257-1. **Schemes of microbiome analysis.** Microbiome "omic" data can be processed and analyzed in various ways to address a diverse set of questions concerning the composition, capacity, and function of the microbiome. CNV = copy number variation; OTU = operational taxonomic unit; SNP = single nucleotide polymorphism. (From Noecker C, McNally CP, Eng A, Borenstein E. High-resolution characterization of the human microbiome. *Transl Res*. 2017;179:10-23.)



E-FIGURE 257-2. **Factors shaping the neonatal microbiome.** Maternal vaginal infections or periodontitis can result in bacteria invading the uterine environment. Delivery mode shapes the initial bacterial inoculum of the newborn. Postnatal factors such as antibiotic use, diet, genetics, and environmental exposure further configure the microbiome during early life. As diet diversifies with age, the microbiome gradually shifts toward an adult-like configuration, which is usually reached by age 3 years. (From Tamburini S, Shen N, Wu HC, Clemente JC. The microbiome in early life: implications for health outcomes. *Nat Med*. 2016;22:713-722.)



E-FIGURE 257-3. Comparison of the microbial composition (A) and predicted function (B) of the microbiota from seven different body sites of healthy individuals from the Human Microbiome Project. There is significant interindividual variation in the community composition, whereas the metabolic function is evenly distributed and prevalent across both individuals and body sites. ATP = adenosine triphosphate; RC = retroauricular crease; tRNA = transfer RNA. (From Human Microbiome Project Consortium. Structure, function and diversity of the healthy human microbiome. *Nature*. 2012;486:207-214.)

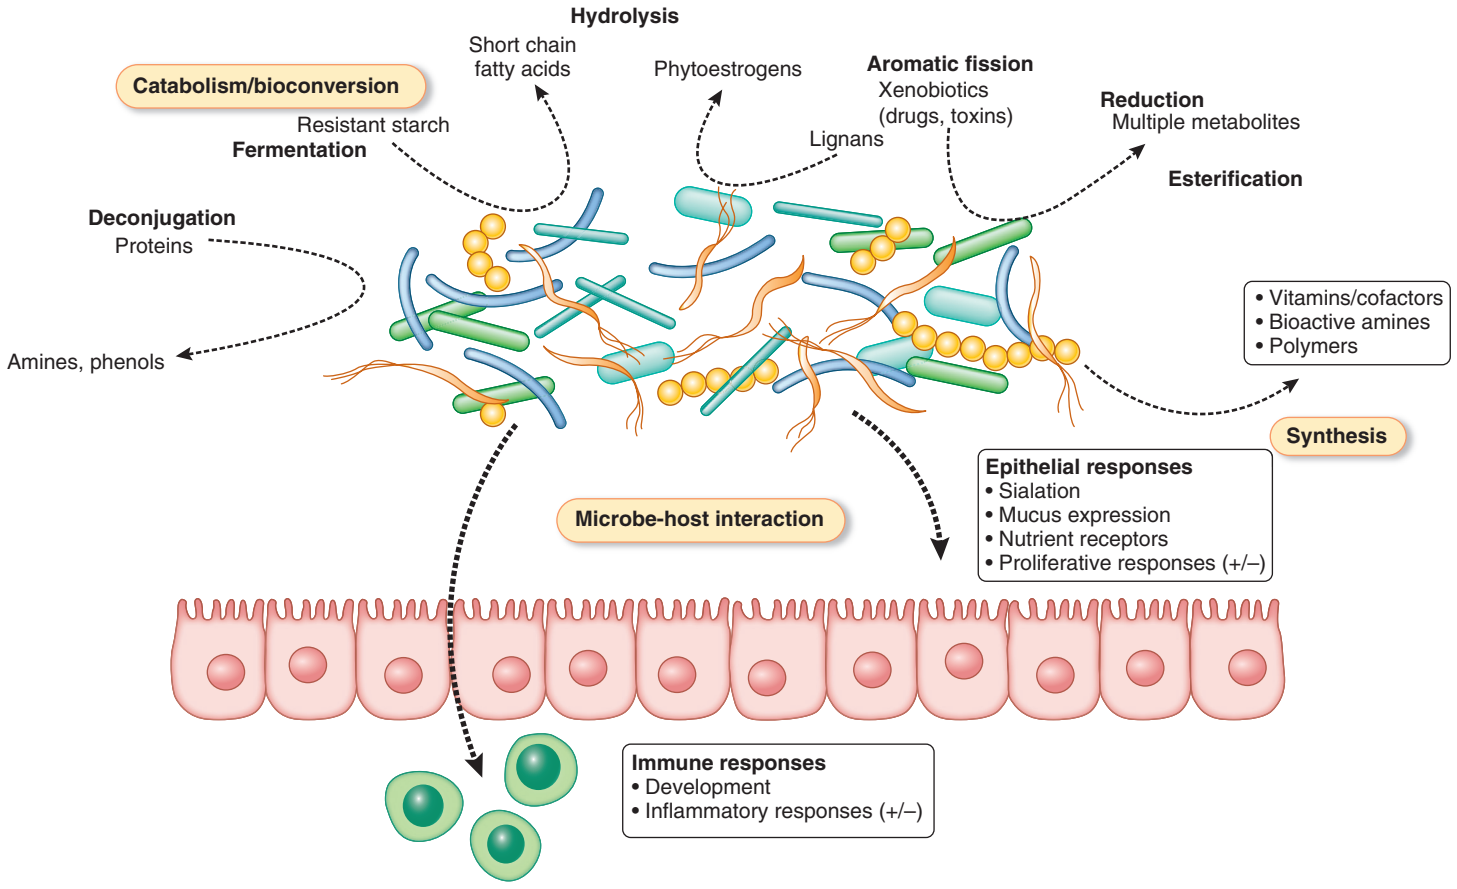


FIGURE 257-2. Potential functions of the indigenous microbiota. The microbiota can have effects through the microbes' synthetic or catabolic metabolic activity or through direct host-microbe interactions. Catabolism and bioconversion of dietary or host-derived compounds can make nutrients more available to the host or alter the bioavailability of drugs. Some members of the microbiota can synthesize important cofactors or bioactive signaling molecules such as amines. Signaling between the microbiota and the host can trigger alterations in host function, such as altered expression of mucus or alteration of the immune response. (From Young VB. The role of the microbiome in human health and disease: an introduction for clinicians. *BMJ*. 2017;356:j831.)

gut microbiota. Additionally, host-derived biomolecules, including bile acids and compounds such as mucous and mucosal secretions, can be substrates for microbial metabolism. Xenobiotics, such as drugs and environmental toxicants, also can be subject to microbe-mediated conversion. In addition to catabolism and bioconversion, microbes can synthesize vitamins and bioactive compounds, such as amines and neurotransmitters (e.g., levodopa). Finally, host-microbe contact can directly alter the function of host tissues. Microbial contact with the immune system and mucosal surfaces, during both postnatal development and maturity, can influence gene expression and thus function of the host.

Given the breadth of functions attributed to the indigenous microbiota, it is clear that alteration of microbiota can lead to disruption of homeostasis. This disruption can be due to loss of a given function, inappropriate expression of a function in time or space, or introduction of maladaptive functions (Table 257-1). These mechanisms can involve the host, microbes (both resident and invasive), and environmental factors. The latter can include factors such as medications, notably antibiotics, and surgical procedures that can alter anatomy or introduce foreign material.

DISEASE ASSOCIATIONS

The microbiome is associated with a wide range of conditions, although cause and effect are often difficult to establish.

OBESITY

The microbiota can directly influence the metabolism of its host through a variety of mechanisms (Fig. 257-3).[8] In addition to increased energy harvest, altered metabolic signaling and altered inflammatory tone combine with diet to allow the microbiota to modulate multiple pathways that can lead to obesity (Chapter 201). Obesity in people and experimental animals is associated with an altered microbiota composition. Despite these observational findings, transfer of a normal fecal microbiome into obese individuals does not appear to result in weight loss.[A1]

TABLE 257-1 FACTORS THAT CAN ALTER THE STRUCTURE AND FUNCTION OF THE MICROBIOTA

HOST FACTORS
Birth mode
Genetics
Gender
Immune status
Age
Preexisting disease
Anatomic disruption (e.g., gastrointestinal surgery, implantation of medical devices)
ENVIRONMENTAL/IATROGENIC FACTORS
Diet
Residence (urban vs. rural)
Animal exposure (including pets)
Environmental toxicants (naturally occurring or humanmade)
Antibiotics
Other drugs (e.g., chemotherapy, proton pump inhibitors, anti-inflammatory drugs)
MICROBIAL FACTORS
Infections (viral, bacterial, fungal, helminthic)
Ingestion of fermented foods (e.g., yogurt, kimchee, kefir)
Use of probiotic organisms

INFLAMMATORY BOWEL DISEASE

Evidence for a potential role for gastrointestinal microbiota in inflammatory bowel disease (Chapter 127) is based on culture data[9] and the disease's occasional response to antibiotics. Polymorphisms in genes that are involved in sensing and responding to microbes, including the nucleotide-binding oligomerization domain-containing protein 2 (*NOD2*) are associated with

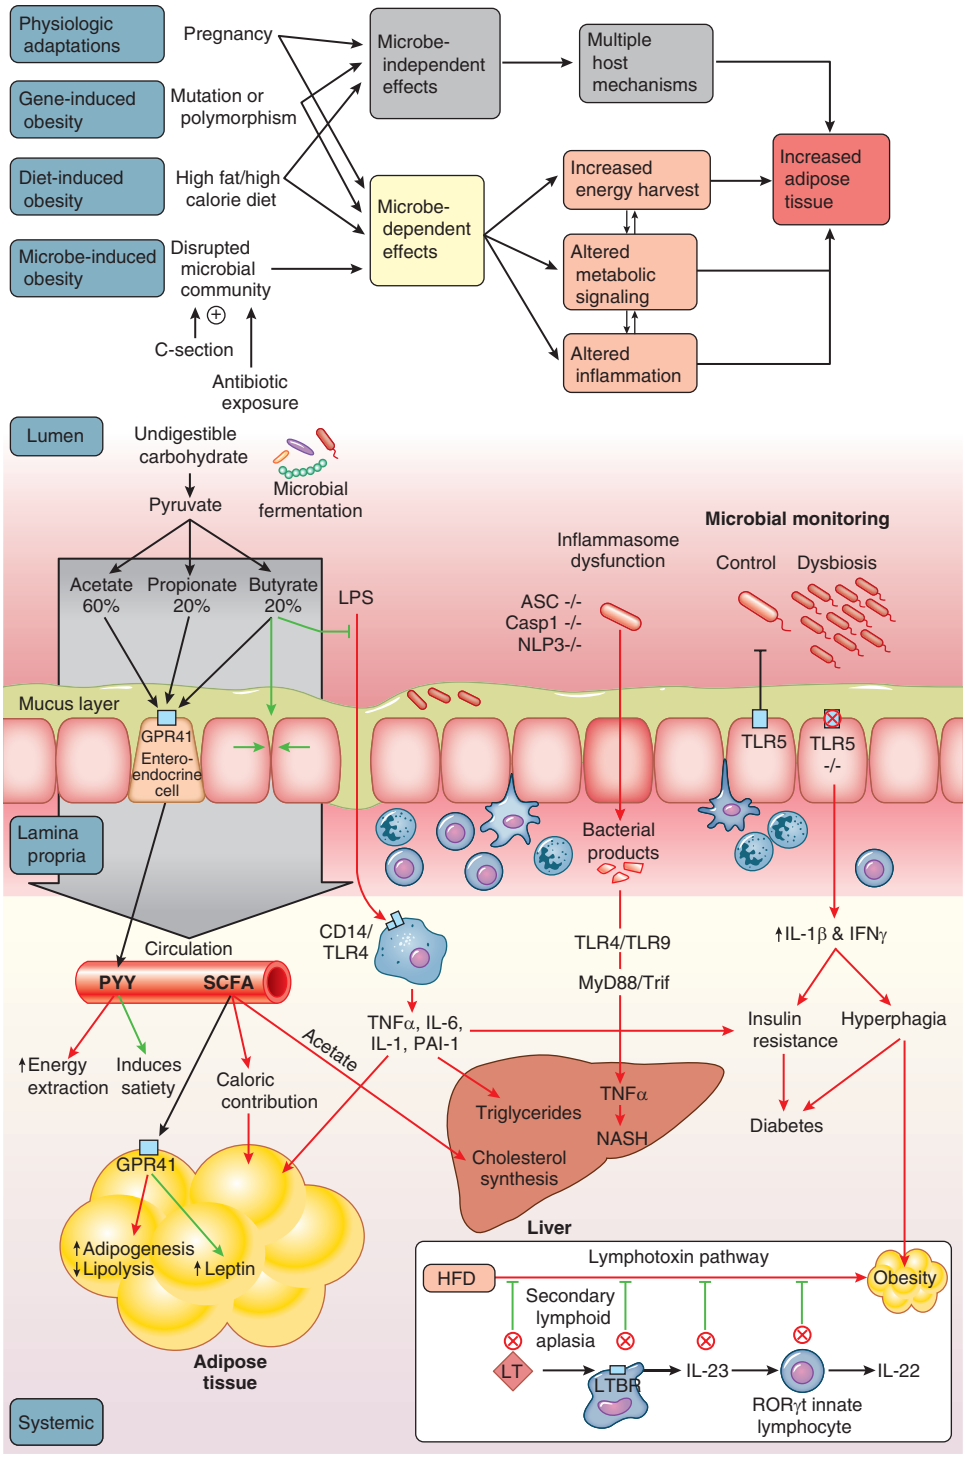

FIGURE 257-3. Mechanisms by which the microbiota can influence host metabolism. Undigested carbohydrates are fermented by the intestinal microbiota to short-chain fatty acids (SCFAs). SCFAs can signal to the host and modify metabolic activity. SCFAs are readily absorbed, contribute up to 10% of caloric intake, and can increase adipogenesis by binding GPR41 on adipocytes. Changes in inflammatory tone (e.g., via LPS stimulation) increase weight gain, total body and liver adiposity, and insulin resistance. (*Inset*) Deleting any component of the lymphotoxin pathway results in loss of control of the microbiome and blocks the ability of mice to gain weight on a high-fat diet. Cohousing lymphotoxin B receptor (LTBR)-deficient and wild-type (WT) mice restores diet-induced obesity and partially restores a WT/high-fat diet (HFD) microbiota. IFN = interferon; IL = interleukin; LPS = lipopolysaccharide; LT = lymphotoxin; NASH = nonalcoholic fatty liver disease; PAI-1 = plasminogen activator inhibitor 1; PYY = polypeptide YY; TNF = tumor necrosis factor; TLR = toll-like receptor. (From Cox LM, Blaser MJ. Pathways in microbe-induced obesity. *Cell Metab*. 2013;17:883-894.)

increased risk for inflammatory bowel disease, thereby providing further evidence for a microbial role in pathogenesis, likely by initiating and modulating mucosal immune responses.

The indigenous microbiota also is significantly different between patients with the disease and controls. Although these associations cannot prove causality, data suggest that the microbiota itself can initiate the dysregulated inflammatory response that is seen in inflammatory bowel disease in individuals with a genetic predisposition to this type of response. This observation emphasizes that the microbiota is part of a complex system of interrelated factors, including the host, the indigenous microbes, and the environment, all of which intersect to influence the homeostasis of the entire system.[10]

C. DIFFICILE INFECTION

Among the most dramatic examples of the unintended consequences of antimicrobial agents is the "collateral damage" to the indigenous microbiota. Perhaps the best example is the rise of *C. difficile* as the cause of the majority of cases of antibiotic-associated colitis.

The normal microbiota can prevent colonization and disease by *C. difficile* through a variety of mechanisms, including competition for nutrients, stimulation of host responses, and alterations of key aspects of the physiology of the organism, such as germination of spores and vegetative outgrowth with toxin production.[11] Disruption of the indigenous microbiota by antibiotics can lead to susceptibility to *C. difficile* infection (E-Fig. 257-4). *C. difficile* infection is also the best example of the potential to restore normal function by intentionally manipulating the altered microbiota.

COLON CANCER

The distal gastrointestinal tract, which harbors the largest and densest population of microbes in the human body, is where the indigenous colonic microbes are able to catalyze a large number of biotransformations that could alter susceptibility to the development of colorectal cancer.[12] For example, these intestinal microbes play a key role in the metabolism of nitrosamines and polycyclic amines, both of which can have carcinogenic activity.[13] Conversely, fermentation of nondigestible carbohydrates by the intestinal microbiota can lead to the production of short-chain fatty acids, such as butyrate, which has anti-inflammatory and antitumor activities. Furthermore, mucosal inflammation initiated by intestinal infection may play a key role in initiating the process that leads to cancer.

ASTHMA

Cesarean delivery and early exposures to antibiotics are associated with increased risk of asthma, whereas breast-feeding has a protective association. The hygiene hypothesis suggests that the microbiota may be involved in a causal pathway because these neonatal and childhood exposures have been observed to be associated with variation in the bacterial microbiota.

NEUROLOGIC DISORDERS

Changes in the gut microbiota have been associated with a variety of neurologic conditions, including autism, depression, and multiple sclerosis. As with many other associations, however, a causal relationship remains to be proven.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

In patients who have undergone hematopoietic stem cell transplantation (Chapter 163), loss of fecal diversity and domination by a single taxa at the time of engraftment are associated with substantially increased mortality compared with higher diversity.[14] Growth of enterococci, which are dependent on lactose, also may exacerbate graft-versus-host disease.[15]

Although observational data suggest that repletion of a normal intestinal microbiome may be beneficial to prevent graft-versus-host disease, clinical recommendation must await randomized trials.

THERAPIES TARGETING THE MICROBIOME

Based on associations of an altered structure and function of the microbiota with various diseases, intentional modulation of the indigenous microbiota could represent a novel strategy for prevention and treatment (Table 257-2).[16] The best evidence for intentionally targeting the microbiota with therapeutic intent has been the setting of recurrent *C. difficile* infection,[17] where fecal transplantation has about an 80% efficiency for reducing recurrences[A2] and oral ingestion of live purified Firmicutes bacterial spores has about a 70% efficacy for reducing recurrent infection.[A3] The protection of the intestinal microbiota with probiotics, in the form of fermented foods and microbes isolated from fermented foods, such as lactobacilli and yeasts, also can reduce antibiotic-induced diarrhea.[A4]

Fecal transplantation also has shown benefit in the treatment of severe malnutrition.[18] For young children with moderate acute malnutrition, a microbiota-directed dietary supplement can significantly improve weight gain and markers of nutrition.[A5] By comparison, fecal transplantation has had variable and unclear impact on patients with ulcerative colitis,[A6,A7] for whom it is currently considered to be a promising but not yet standard therapy (Chapter 127).[19] For irritable bowel syndrome (Chapter 123), the benefit of probiotics is inconclusive,[20] but transplantation of the fecal microbiome may reduce symptoms in some patients with predominant abdominal bloating.[A8]

TABLE 257-2 STRATEGIES FOR TARGETING THE MICROBIOTA THERAPEUTICALLY

ADMINISTRATION OF MICROBES
Fecal microbiota transplantation
Single-agent probiotics
Designer microbial communities (multispecies probiotics)
Bacteriophage therapy
MODULATION OF EXISTING MICROBES IN A COMMUNITY
Microbial nutrients (prebiotics)
Antibiotics

CONCLUSIONS

The microbiome is an exciting component of the role that microbes play in health and disease. Assessment of the functional status of the indigenous microbiota and therapeutic manipulation of the microbiome is likely to be a key part of the developing paradigm of precision medicine (E-Fig. 257-5) that has the potential to alter the practice of medicine radically now and in the future.

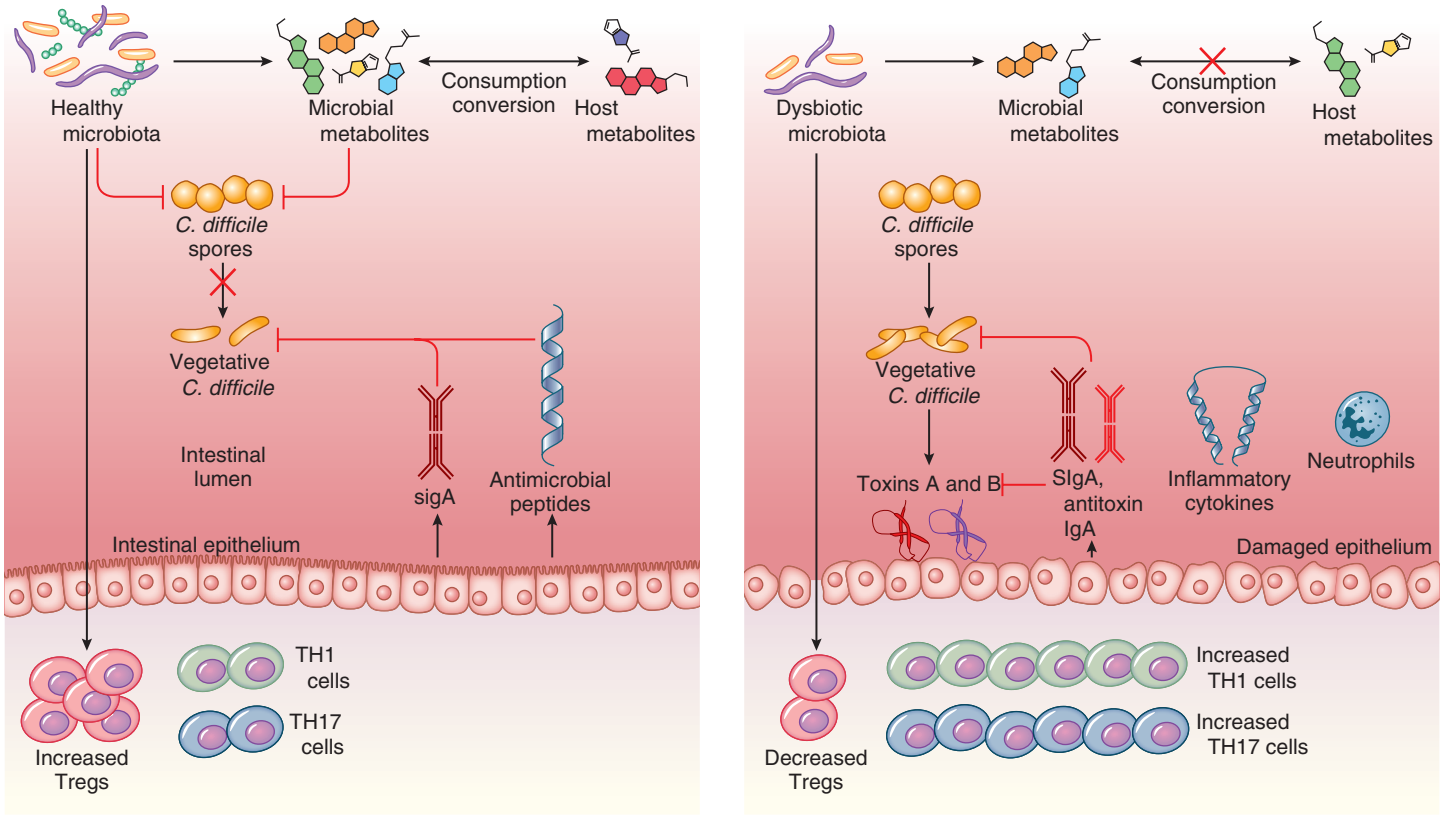
258 PRINCIPLES OF ANTI-INFECTIVE THERAPY

LOUIS B. RICE

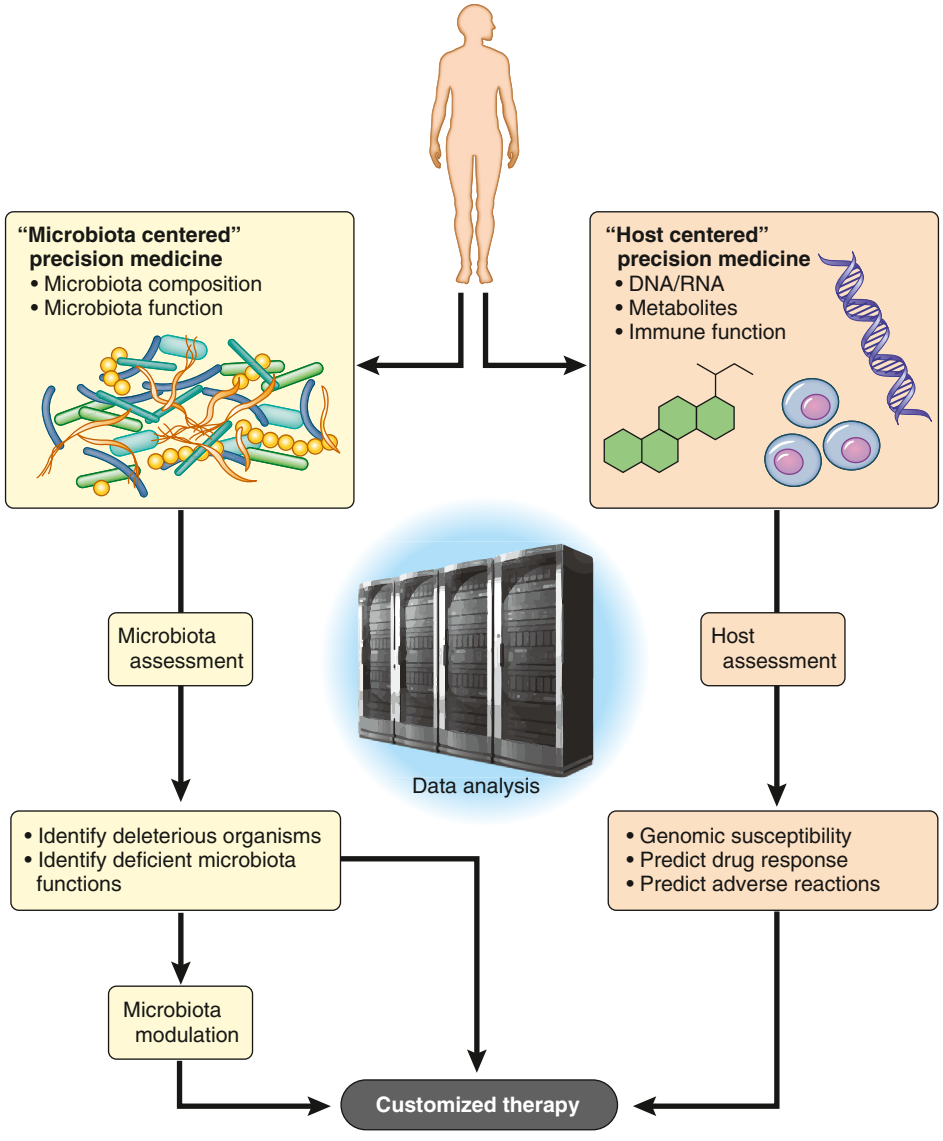
SELECTING ANTIMICROBIAL THERAPY

EMPIRICAL ANTIMICROBIAL THERAPY

It is rare that antimicrobial therapy is instituted for a serious infection with full knowledge of the identity and antibiotic susceptibilities of the specific pathogen, so empirical antibiotic therapy typically must be initiated based on presumptions regarding the nature of the infection. The first challenge is to assess whether the patient likely has an infection and, if so, where is it located. The patient's clinical manifestations or syndromes may not be infectious. Autoimmune diseases (Chapter 236), lymphomas (Chapters 171 and 172), drug reactions (Chapter 234), hematomas, and deep vein thromboses (Chapter 68) often present with fever as a cardinal symptom, so it is important to keep in mind that empirical antibiotics may not be needed. In other situations, a careful history, thorough physical examination, and a few laboratory tests will allow identification of a clinical syndrome, such as meningitis (Chapter 381), pneumonia (Chapter 85), urinary tract infection (Chapter 263), enteric infection (Chapter 262), or sexually transmitted disease (Chapter 264). Some infectious syndromes, such as upper respiratory tract infections (Chapter 84),



E-FIGURE 257-4. Proposed mechanisms of the microbiota on pathogen resistance and the host during *Clostridioides difficile* infection. (**A**) Both microbial and host factors can inhibit germination and growth of *C. difficile*. A healthy microbiota is capable of consuming both microbial and host-generated metabolites, limiting the growth of *C. difficile*. Cross-talk between the microbiota and the host immune system results in a regulated immune response. Furthermore, the microbiota can stimulate production of antimicrobial peptides and secretory immunoglobulin A (SIgA), which can maintain the composition of the microbiota. (**B**) Disruption of the microbiota, due to factors such as antibiotic use, drugs, diet, or inflammation, can lead to the development of *C. difficile* infection. A dysbiotic microbiota can result in the loss of colonization resistance due to changes in the structural and/or metabolic environment. The loss of specific community members potentially affects the levels of microbial and host-generated metabolites, resulting in a different functional state that promotes spore germination and vegetative outgrowth. A dysbiotic microbiota may also result in an imbalanced immune response through the loss of immune regulation and a proinflammatory state, both of which may affect disease development. Toxin production by vegetative *C. difficile* can stimulate the production of inflammatory cytokines, neutrophils, and antitoxin antibodies. Ig = immunoglobulin; SIgA = secretory IgA; Tregs = regulatory T cells. (From Seekatz AM, Young VB. *Clostridioides difficile* and the microbiota. *J Clin Invest*. 2014:124:4182-4189.)



E-FIGURE 257-5. Incorporation of the microbiota into the developing precision medicine paradigm. As currently being developed, precision medicine proposes to determine responses to treatment according to the assessment of human genomics, metabolism, and immune function. On the basis of these data, susceptibility to disease, response to treatment, and potential adverse reactions can be predicted and a customized therapy designed. Because the microbiota can also influence this same susceptibility and response to treatment, we propose that assessment of the microbiota also could be incorporated into a complete precision medicine approach. (From Young VB. The role of the microbiome in human health and disease: an introduction for clinicians. *BMJ*. 2017;356:j831.)

The normal microbiota can prevent colonization and disease by *C. difficile* through a variety of mechanisms, including competition for nutrients, stimulation of host responses, and alterations of key aspects of the physiology of the organism, such as germination of spores and vegetative outgrowth with toxin production.[11] Disruption of the indigenous microbiota by antibiotics can lead to susceptibility to *C. difficile* infection (E-Fig. 257-4). *C. difficile* infection is also the best example of the potential to restore normal function by intentionally manipulating the altered microbiota.

COLON CANCER

The distal gastrointestinal tract, which harbors the largest and densest population of microbes in the human body, is where the indigenous colonic microbes are able to catalyze a large number of biotransformations that could alter susceptibility to the development of colorectal cancer.[12] For example, these intestinal microbes play a key role in the metabolism of nitrosamines and polycyclic amines, both of which can have carcinogenic activity.[13] Conversely, fermentation of nondigestible carbohydrates by the intestinal microbiota can lead to the production of short-chain fatty acids, such as butyrate, which has anti-inflammatory and antitumor activities. Furthermore, mucosal inflammation initiated by intestinal infection may play a key role in initiating the process that leads to cancer.

ASTHMA

Cesarean delivery and early exposures to antibiotics are associated with increased risk of asthma, whereas breast-feeding has a protective association. The hygiene hypothesis suggests that the microbiota may be involved in a causal pathway because these neonatal and childhood exposures have been observed to be associated with variation in the bacterial microbiota.

NEUROLOGIC DISORDERS

Changes in the gut microbiota have been associated with a variety of neurologic conditions, including autism, depression, and multiple sclerosis. As with many other associations, however, a causal relationship remains to be proven.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

In patients who have undergone hematopoietic stem cell transplantation (Chapter 163), loss of fecal diversity and domination by a single taxa at the time of engraftment are associated with substantially increased mortality compared with higher diversity.[14] Growth of enterococci, which are dependent on lactose, also may exacerbate graft-versus-host disease.[15]

Although observational data suggest that repletion of a normal intestinal microbiome may be beneficial to prevent graft-versus-host disease, clinical recommendation must await randomized trials.

THERAPIES TARGETING THE MICROBIOME

Based on associations of an altered structure and function of the microbiota with various diseases, intentional modulation of the indigenous microbiota could represent a novel strategy for prevention and treatment (Table 257-2).[16] The best evidence for intentionally targeting the microbiota with therapeutic intent has been the setting of recurrent *C. difficile* infection,[17] where fecal transplantation has about an 80% efficiency for reducing recurrences[A2] and oral ingestion of live purified Firmicutes bacterial spores has about a 70% efficacy for reducing recurrent infection.[A3] The protection of the intestinal microbiota with probiotics, in the form of fermented foods and microbes isolated from fermented foods, such as lactobacilli and yeasts, also can reduce antibiotic-induced diarrhea.[A4]

Fecal transplantation also has shown benefit in the treatment of severe malnutrition.[18] For young children with moderate acute malnutrition, a microbiota-directed dietary supplement can significantly improve weight gain and markers of nutrition.[A5] By comparison, fecal transplantation has had variable and unclear impact on patients with ulcerative colitis,[A6,A7] for whom it is currently considered to be a promising but not yet standard therapy (Chapter 127).[19] For irritable bowel syndrome (Chapter 123), the benefit of probiotics is inconclusive,[20] but transplantation of the fecal microbiome may reduce symptoms in some patients with predominant abdominal bloating.[A8]

Antibiotics

CONCLUSIONS

The microbiome is an exciting component of the role that microbes play in health and disease. Assessment of the functional status of the indigenous microbiota and therapeutic manipulation of the microbiome is likely to be a key part of the developing paradigm of precision medicine (E-Fig. 257-5) that has the potential to alter the practice of medicine radically now and in the future.

258 PRINCIPLES OF ANTI-INFECTIVE THERAPY

LOUIS B. RICE

SELECTING ANTIMICROBIAL THERAPY

EMPIRICAL ANTIMICROBIAL THERAPY

It is rare that antimicrobial therapy is instituted for a serious infection with full knowledge of the identity and antibiotic susceptibilities of the specific pathogen, so empirical antibiotic therapy typically must be initiated based on presumptions regarding the nature of the infection. The first challenge is to assess whether the patient likely has an infection and, if so, where is it located. The patient's clinical manifestations or syndromes may not be infectious. Autoimmune diseases (Chapter 236), lymphomas (Chapters 171 and 172), drug reactions (Chapter 234), hematomas, and deep vein thromboses (Chapter 68) often present with fever as a cardinal symptom, so it is important to keep in mind that empirical antibiotics may not be needed. In other situations, a careful history, thorough physical examination, and a few laboratory tests will allow identification of a clinical syndrome, such as meningitis (Chapter 381), pneumonia (Chapter 85), urinary tract infection (Chapter 263), enteric infection (Chapter 262), or sexually transmitted disease (Chapter 264). Some infectious syndromes, such as upper respiratory tract infections (Chapter 84),

ABSTRACT

The introduction of antimicrobial agents into clinical use has increased life expectancy and allowed more aggressive treatment of trauma, malignancies, and organ failure. The use of antibiotics in agriculture has enhanced the productivity of both meat and vegetable producers, thereby allowing many more people around the world to be fed. Unfortunately, the general safety of most antimicrobials has made it tempting to use them indiscriminately, with the resulting emergence and spread of multidrug-resistant microorganisms.

The emergence of antimicrobial resistance in human pathogens was predictable and unavoidable, given their rapid replication (offering frequent opportunities for mutation of antimicrobial targets) and frequent genetic exchange. The rapidity of the widespread dissemination of resistance was, however, avoidable, and best practices can limit or potentially even somewhat reverse this problem.

may be sufficiently likely to be caused by virus such that antibiotics are likely to be of no value.

After the infectious syndrome is identified, the next step is to make a reasonable estimation of the specific pathogens that are likely to be involved. Appropriate empiric therapy is especially important when delayed effective antimicrobial coverage is associated with worse clinical outcomes,[1] such as for community-acquired pneumonia (Chapter 85), central nervous system infections (Chapters 381 to 383), and sepsis[2] (Chapter 94). In an adult patient with suspected bacterial meningitis (Chapter 381), for example, ceftriaxone covers both of the two most likely pathogens, *Streptococcus pneumoniae* (Chapter 268) and *Neisseria meningitidis* (Chapters 274). If the patient is elderly, pregnant, or otherwise at high risk if the pathogen is *Listeria monocytogenes* (Chapter 272), the regimen could be expanded to include ampicillin. If there is a reason to suspect *S. pneumoniae* with reduced susceptibility to ceftriaxone, vancomycin may be added. Finally, if the clinical picture is equivocal and includes the possibility of encephalitis, acyclovir might be added to address the possibility of herpes simplex encephalitis (Chapters 345 and 383). The difficulty of distinguishing among pathogens when treating community-acquired pneumonia (Chapter 85) leads many to prescribe both ceftriaxone (for *S. pneumoniae* [Chapter 268] and *Haemophilus influenzae* [Chapter 277]) and azithromycin (for atypical pathogens *Legionella pneumophila* [Chapter 290], *Chlamydia pneumoniae* [Chapter 294], and *Mycoplasma pneumoniae* [Chapter 293]). Conversely, if a patient presents with a community-acquired pyelonephritis (Chapter 263), *Escherichia coli* (not *S. pneumoniae*) should be at the top of the list. The likely pathogens can then guide what antimicrobial agent(s) to administer.

This syndrome to pathogen to antimicrobial agent thought process is designed to allow identification of an antibiotic regimen that is as targeted as possible, so as to have less impact on the resident flora and a lower likelihood of promoting the emergence of resistance. For example, a typical cellulitis will be most often caused by *Streptococcus pyogenes*, and less commonly, by *Staphylococcus aureus*. These two pathogens could be adequately treated by nafcillin (which has only relatively narrow gram-positive coverage) or by ampicillin-sulbactam (which has broad coverage that includes facultative and anaerobic gram-negative bacilli and a wide range of gram-positive cocci). It is obviously preferable to avoid killing the facultative gram-negative and anaerobic bacteria in the gastrointestinal tract, especially when the likelihood that they are responsible for the infection is very low. Conversely, very broad antibacterial coverage may be critical to success in other situations, such as treating an intra-abdominal infection from a perforated appendix (Chapter 128), a situation in which the polymicrobial microbiology of the likely infection will never be precisely delineated.

When considering empirical coverage, it is useful to have as much information as possible. Relevant information might include a Gram stain of material from the site of the infection. When Gram stains are not available or relevant, specific or multiplex polymerase chain reaction (PCR) amplification may give a sense of whether broader coverage is necessary.

The other major consideration in choosing an empirical regimen is the condition of the patient. If the patient is febrile but awake and fully functional, the empirical regimen can be more parsimonious, unless the situation worsens acutely. Conversely, the margin for error is much less in septic shock (Chapter 94), for which broad coverage for all conceivable pathogens is indicated until more information is obtained.

Unfortunately, real-life clinical scenarios can be challenging. For example, the severity of a patient's illness may be due to noninfectious causes, and few antibiotics are truly narrow-spectrum. As a result, the best strategy to prevent antimicrobial side effects and the emergence of resistance is to minimize exposure to antibiotics by treating only infections likely to respond to antibiotics with the right dose for the shortest effective duration possible.

DEFINITIVE ANTIMICROBIAL TREATMENT

Definitive therapy requires the identification of a pathogen (or pathogens) responsible for the infection as well as their susceptibility to specific antimicrobial agents. This task is sometimes relatively straightforward (e.g., multiple blood cultures growing *S. aureus* in a patient with clinical and imaging evidence of endocarditis) and sometimes more complicated (e.g., growing coagulase-negative staphylococci, *S. pyogenes*, *Pseudomonas aeruginosa*, and *Bacteroides fragilis* from deep cultures of a diabetic foot ulcer). Once the pathogen(s) are identified and the susceptibility to antimicrobial agents is determined, empirical broad-spectrum therapy often can be narrowed to less toxic, less complicated, or less expensive agents. In some circumstances, it may be possible to switch from a parenteral to an oral regimen, thereby reducing the risks associated with an intravenous catheter and perhaps shortening the patient's duration of hospitalization. Alternatively, culture and susceptibility testing may guide expanded regimens to include coverage for an unanticipated or resistant pathogen.

Whenever a regimen is chosen, the clinician should also consider the potential next alternative antimicrobial therapy if the first choice must be discontinued because of an allergic reaction or drug toxicity prior to completing the therapeutic course. Such contingencies should be considered in advance because they may impact the original choice of antibiotic. For example, if a patient develops a rash while being co-administered both a penicillin and a cephalosporin, both classes of drugs may need to be avoided.

Susceptibility Testing

A cornerstone of the treatment of infectious diseases is in vitro susceptibility to determine the ability of a microorganism to grow in the presence of serial dilutions of a variety of potentially useful antimicrobial agents. In standard susceptibility tests, serial dilutions of a given antibiotic are made in either broth or agar, and then a specified number of bacteria are inoculated into (broth) or onto (agar) the media and incubated at temperatures and other conditions (e.g., aerobic and anaerobic) permissive for growth. Growth is determined by visual inspection after 16 to 24 hours. The lowest antibiotic concentration at which no visible growth is seen is defined as the minimal inhibitory concentration (MIC). An alternative agar-based test is the disc diffusion assay, in which a paper disc containing a fixed concentration of an antibiotic is placed onto an agar plate previously spread with a specified number of bacteria. The antibiotic diffuses into the agar and inhibits growth of the strain at distances with sufficient concentrations of diffused antibiotic. Zone sizes are measured, and susceptibility is inferred. Another alternative is the E-test, in which a strip containing a gradient of the antibiotic is placed on an agar plate that was previously inoculated with the bacteria.

Each licensed antibiotic has a defined minimal inhibitory concentration that classifies an organism as "susceptible" or "resistant" (and sometimes as "intermediate" as well). These determinations are based on obtainable blood and tissue levels in vivo to assist the clinician in understanding the minimal inhibitory concentration number and its therapeutic implications. However, designations of "susceptible" and "resistant" are best understood as general guides, because exceptions can result in an unnecessary limitation of options in some cases and inadequate therapy in others. For example, the minimal inhibitory concentrations of a typical strain of *P. aeruginosa* (Chapter 282) fall well outside of the susceptible range for tetracycline, but tetracycline is so heavily concentrated in the urine that it achieves levels that exceed even the elevated minimal inhibitory concentrations of *P. aeruginosa* and can successfully treat *P. aeruginosa* cystitis. Conversely, pneumonia strains caused by *S. pneumoniae* with an minimal inhibitory concentration of 2 μg/mL would be readily treatable with intravenous ceftriaxone, but ceftriaxone's limited penetration into the cerebrospinal fluid (CSF) would mean that strain would be considered resistant to ceftriaxone for treating meningitis. Fine distinctions such as these are best made by expert consultants.

A final point about susceptibility is that it may be dependent on the inoculum of bacteria that are used in the assay. In most cases, a standardized quantity of bacteria is added when performing susceptibility testing. If that inoculum is increased 100-fold, the MIC may increase dramatically, as is often seen with extended-spectrum, β-lactamase–producing Enterobacteriaceae and cephalosporins. As such, it is sometimes important to estimate the inoculum of bacteria as well as the likely penetration of the antibiotic when determining whether an antibiotic that shows in vitro activity will be effective clinically. For example, a dense pneumonia, in which the bacterial inoculum is likely to be very high, may not respond to the same antibiotics that would be quite effective for treating a low-inoculum urinary tract infection caused by the same strain.

Many modern bacteriology laboratories now use automated approaches or genotypic methods, such as PCR[3] testing, to identify bacterial polymorphisms that are indicative of antibiotic resistance. These panels more rapidly provide information when they identify a resistance gene, but they are limited by the fact that they can only find the genes in the panel and not any novel resistance genes. Although use of these panels has not been shown to improve clinical outcomes,[A1] they are quite helpful when looking for specific pathogens, such as identifying nasal colonization with methicillin-resistant *S. aureus* (Chapter 267) or detecting herpes simplex (Chapter 345) as a cause of viral encephalitis (Chapter 383). Matrix-assisted laser desorption ionization–time of flight mass spectrometry is an alternative to PCR detection methods.

BACTERICIDAL ACTIVITY

Standard susceptibility assays test the ability of the antibiotic to inhibit further growth of the microorganism but do not indicate whether the strain is killed by the antibiotic. Most antibiotics are characteristically either bacteriostatic (inhibit growth) or bactericidal (inhibit and kill), but the characteristics may vary with the antibiotic-pathogen pair. Bactericidal activity is determined using time-kill assays, which assess the degree to which an inoculum of bacteria is reduced after a 24-hour period; a greater than 99.9% reduction in the inoculum is required to be designated bactericidal. Fortunately, successful treatment of most infections requires only that the pathogen be inhibited, thereby allowing the immune system time to clear the infection, so bactericidal therapy is not crucial for most infections.[A2] In some situations, however, such as in endocarditis (with poor penetration of the immune system into the vegetation), in meningitis (a desire for rapid killing to preserve brain function), and often in osteomyelitis (poor penetration and dormant state of bacteria), bactericidal therapy yields a higher degree of success than bacteriostatic therapy.

TARGETING ANTIMICROBIAL THERAPY APPROPRIATE TO THE INFECTION AND THE PATIENT

Nature of the Infection

The conditions under which antimicrobial agents are tested for activity against bacteria in the laboratory are very different from the conditions of an actual human infection, and it is remarkable that in vitro susceptibility correlates well with clinical efficacy in many clinical infections. In considering the optimal choice of agent(s), an important first determination is whether the antibiotic will reach the location of the infection in concentrations sufficient to inhibit the infecting microorganisms. For example, the fluoroquinolone antimicrobial agent norfloxacin can be used only to treat urinary tract infections because the urine is the only body fluid in which it achieves sufficient concentrations to be effective. Conversely, the fluoroquinolone moxifloxacin is effective for many infections but is not recommended for urinary tract infections because it does not achieve sufficient concentrations in the urine. These determinations are sometimes species dependent. For example, *Enterococcus faecalis* (Chapter 270) generally has MICs for the fluoroquinolone ciprofloxacin ranging from 1 to 4 μg/mL. Given the concentrations that ciprofloxacin achieves in the urine, it is a reasonable choice for treatment of a urinary tract infection (Chapter 263) caused by a susceptible strain. However, since serum concentrations of ciprofloxacin at peak are generally in the 2 μg/mL range, it is not adequate for treating tissue enterococcal infections.

The local environment can also have an impact. For example, daptomycin is not sufficiently effective in treating pneumonia because it is inactivated when it complexes with surfactant in the alveoli.

Another major consideration when treating a clinical infection is the state of the microorganisms in the infection. Bacteria reduce their rate of growth when present in a large inoculum, and some antibiotics, notably β-lactams, are more effective at killing bacteria when they are multiplying rapidly and hence may be less effective in some high-inoculum infections. Under many conditions, bacteria also form biofilms, which are carbohydrate/DNA/water matrices that impair the action of antibiotics through a variety of mechanisms, including altered metabolic activity of the microorganism and reduced access for the antibiotic. Under certain circumstances (for example, in chronic osteomyelitis; Chapter 251), *S. aureus* strains can form "small colony variants," which are also metabolically different and respond poorly to many antimicrobials. Finally, there is the phenomenon known as "persisters," a minute percentage of a large original inoculum that for some reason is not killed by the antibiotic and persists to grow again once the antimicrobial pressure has subsided. Antimicrobial therapies for these altered states are quite limited in their effectiveness, thereby emphasizing the importance of reducing the inoculum of infection by drainage or debridement whenever possible.

Infection of prosthetic material presents a major challenge. Access of antibiotics to the infection site is often limited by both physical barriers and biofilms. Prosthetic joints, prosthetic cardiac valves, intravascular stents, and fistulae can all become infected. When possible, all prosthetic material should be removed to facilitate treatment of the infection. In cases in which removal is not a viable option, prolonged therapy (often with combinations of agents that include the rapidly bactericidal agent rifampin) is required, sometimes followed by indefinite suppression with an oral agent active against the infecting strain. The goal of indefinite therapy is not to cure the infection but rather to keep it localized. Although rifampin alone is effective in some of these circumstances, resistance can be generated by just a single point mutation in the RNA polymerase gene, thereby making the emergence of resistance a high-frequency event. For this reason, rifampin should always be used in combination with other agents, although the risk of resistance remains even when used in combination.

Host Factors That Impact Choice or Amount of Antibiotic Prescribed

Allergies

Allergic reactions to antimicrobial agents (Chapter 234) can range from mild rashes to full-blown anaphylaxis (Chapters 233 and 234). A full history must be obtained from the patient before prescribing an antibiotic, and the medical record should be reviewed. Antibiotics for which even mild allergies have been experienced should be avoided if suitable alternatives are available. For β-lactam antibiotics, in the absence of anaphylaxis or a severe allergic reaction such as Steven-Johnson syndrome (Chapter 407), cross-allergy among penicillins, cephalosporins, and carbapenems are sufficiently infrequent that substitution of one class for the other is usually possible. The monobactam aztreonam is the only β-lactam that is safe to use in a patient who has suffered a severe allergic reaction to one of the other classes. In circumstances in which non–β-lactam antibiotics are not a viable option, penicillin desensitization (Chapter 234) can be attempted in controlled, monitored settings.[4] The desensitization should be repeated if subsequent infectious episodes occur that require penicillin treatment.

Pregnancy

An estimated 80% of drugs administered to pregnant women are antibiotics, and about 20 to 25% of pregnant women receive antibiotics. The use of antimicrobial agents in pregnant women requires several additional considerations.[5] The first consideration is the potential that the antimicrobial agent could cause harm to the fetus (Table 258-1). Agents that are commonly used and considered generally safe in pregnancy (most β-lactams, azithromycin, clindamycin, and vancomycin) are considered Category B (safe in animal studies but with no controlled data from humans). For Category C agents, animal studies have shown some reproductive toxicity but well-controlled human studies do not exist; the fluoroquinolones, polymyxins, and sulfamethoxazole fall into this category. Category D agents should not be used because of known human fetal

TABLE 258-1 FDA PREGNANCY CATEGORIES

CATEGORY A
Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters). No antimicrobial agents are in this category.
CATEGORY B
Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women. Antimicrobial classes in this category include most β-lactams, vancomycin, azithromycin, erythromycin, clindamycin, daptomycin, fidaxomicin, fosfomycin, metronidazole, nitrofurantoin, and the antituberculous agents ethambutol and bedaquiline.
CATEGORY C
Animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. Antimicrobial agents in this category include imipenem-cilastatin, fluoroquinolones, lipoglycopeptides (dalbavancin, oritavancin, telavancin), clarithromycin, telithromycin, oxazolidinones, polymyxins, sulfamethoxazole, trimethoprim, and the antituberculous agents isoniazid, pyrazinamide, and rifampin.
CATEGORY D
There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. Antimicrobial agents in this category include aminoglycosides, tetracyclines, and tigecycline.
CATEGORY X
Studies in animals or humans have demonstrated fetal abnormalities, and/or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits.

FDA = U.S. Food and Drug Administration.

Source Content and Format of Labeling for Human Prescription Drug and Biological Products; Requirements for Pregnancy and Lactation Labeling (Federal Register/Vol. 73, No. 104/Thursday, May 29, 2008).

toxicity; streptomycin (eighth nerve toxicity) and tetracyclines (incorporation into teeth and bones) are in the D category.

The second consideration is the impact of changes in the metabolism of pregnant women on the pharmacokinetics of various agents. Pregnancy is associated with increases in the volume of distribution of many antibiotics, as well as their renal clearance. These factors can reduce overall antibiotic exposure, especially for agents that have substantial protein binding, such as ceftriaxone, or narrow therapeutic margins, such as the aminoglycosides. As a result, increased dosing may be required to achieve target levels of the antibiotic at the site of infection.

The final consideration when administering antibiotics to pregnant women is the potential effects on the fetal microbiota. Several studies have documented profound changes in fetal microbiota in response to antimicrobial administration to the mother. At present, the long-term impacts of these microbiota changes on the child are not known, but concerns exist regarding immune development and risk for immunologically mediated diseases such as asthma.

Age

The pharmacokinetics and pharmacodynamics of antimicrobial agents are not uniform across all age groups. In older individuals, the absorption of oral antimicrobials may be altered if their absorption depends on gastric pH, since relative or absolute achlorhydria is more common after age 60 years. Absorption of antimicrobials such as oral penicillin, which is deactivated by gastric acid, may be higher in the elderly, whereas agents that require gastric acid for absorption (e.g., ketoconazole) may be less well absorbed. Fluoroquinolones are contraindicated in elderly patients with renal insufficiency owing to the risk of torsades de pointe.

Renal and Hepatic Function

The two major routes of elimination of antibiotics are through the kidneys and the liver. An assessment of renal function, generally as calculated by the creatinine clearance, is important for the proper dosing of many antibiotics, especially when the therapeutic range is relatively narrow. For example, aminoglycosides are predominantly excreted through the kidney and have a narrow margin of safety, with nephrotoxicity and ototoxicity associated with serum concentrations that are not dramatically higher than therapeutic levels. With standard three times per day dosing, it is important to measure serum concentrations of aminoglycosides, to monitor renal function, and to adjust the dose as necessary. The bactericidal activity of aminoglycosides is most pronounced when maximum peak serum concentrations are achieved, and their toxicity is commonly associated with elevated trough levels. In some instances, it is possible to administer aminoglycosides as a once-daily dose, thereby achieving a much higher peak and a much lower trough concentration. Vancomycin also has been associated with nephrotoxicity, especially if it is administered in conjunction with an aminoglycoside. Serum concentrations of vancomycin are often measured to ensure that trough levels minimize the risks of toxicity. For most other antimicrobial agents, the margins of safety are considerably greater, so adjustments for renal insufficiency, if they are necessary, can be made empirically without measuring specific serum concentrations (see Stanford Health Care Antimicrobial Dosing Reference Guide at med.stanford.edu). Antimicrobial agents that do not require adjustment for renal insufficiency include nafcillin, ceftriaxone, doxycycline, azithromycin, and linezolid.

Antimicrobial agents that are excreted largely or partially by the liver and require dose adjustment in the presence of liver dysfunction include metronidazole, chloramphenicol, tigecycline, caspofungin, and voriconazole. Ceftriaxone, which is heavily concentrated in the bile and can even form stones in pediatric biliary trees, may need dose adjustment for patients with both renal and hepatic dysfunction.

Drug-Drug Interactions

Polypharmacy is a major problem in all hospitals and for many patients with multiple chronic diseases. Virtually all hospitalized patients who are treated with an antimicrobial agent will simultaneously be treated with a variety of other drugs, including other antimicrobials. The clinician must consider other medications that patients may be taking and the potential resulting drug-drug interactions that will amplify or inhibit the activity or toxicity of other agents or the antibiotic itself. One of the most common mechanisms is by interaction with cytochromes that are involved in the metabolism of a variety of drugs. Prominent among these agents are the triazoles that inhibit cytochrome P-450 (voriconazole, itraconazole, posaconazole). Use of these agents can result in excessive levels of other drugs, thereby resulting in toxicity (e.g., quinolones and macrolides are associated with QT prolongation, which can be amplified if they are combined with other drugs for which QT prolongation is also an adverse effect). Ciprofloxacin, which is an inhibitor of CYP1A2, can alter the metabolism of theophylline, clozapine, olanzapine, and caffeine. Linezolid, which is a reversible and nonselective inhibitor of monoamine oxidase, reduces the breakdown of serotonin and can precipitate the serotonin syndrome (Chapter 400) when used with serotonin reuptake inhibitors, opioid analgesics, or antiepileptic drugs. Rifampin, which is frequently included in antituberculosis therapy, induces the cytochrome P-450 system and can result in increased metabolism (and decreased effectiveness) of other medications, including oral contraceptive pills and warfarin.

Development of Resistance

DNA conferring resistance can be transferred between bacteria using transferable plasmids, transposons, bacteriophage, or, in some bacteria, by the uptake of naked DNA. Moreover, some resistance mechanisms (such as multidrug efflux pumps) can confer resistance to several different antimicrobial classes. As such, the best way to prevent resistance in commonly isolated human pathogens is to minimize the exposure to antimicrobials by efforts to avoid antibiotics in patients without bacterial infection, by treating with narrower-spectrum agents whenever possible, by treating patients for only as long as is required to cure the infection, and by strictly adhering to established principles of infection control.

Antimicrobial Combinations

Antimicrobial agents are commonly administered in combinations, and empiric combination therapy is often unavoidable. However, combination therapy carries potentially negative consequences of augmented toxicity (sometimes even a multiplication of the risk of toxicity), drug interactions, and increased selective pressure. Every effort should be made to tailor the regimen when data become available and to focus treatment as soon as it is safe to do so.

Treatment of Polymicrobial Infections

Polymicrobial infection is common in diabetic foot infections (Chapter 210) and intra-abdominal infections (Chapter 128). Diabetes foot infections often include staphylococci, streptococci, facultative and aerobic gram-negative bacilli, and anaerobes. Since the most responsible organism may not be clear, treatment often includes more than one agent, especially if methicillin-resistant *S. aureus* is involved. For intra-abdominal infections, the desire to cover facultative and anaerobic gram-negative rods, as well as anaerobic organisms and enterococci, frequently leads to combination treatment, but these infections can sometimes be adequately covered with a single broad-spectrum agent (such as a carbapenem) or a fixed combination (β-lactam-β-lactamase inhibitor combination).

Minimizing the Emergence of Drug Resistance

Using combinations of antimicrobial agents can prevent the emergence of resistance to either single agent,[6] a principle perhaps best exemplified by the treatment of tuberculosis and human immunodeficiency virus (Chapter 357). For tuberculosis, resistance to isoniazid occurs in about 1 in 10^8 *Mycobacterium tuberculosis* progeny through point mutations in a few different genes, and resistance to rifampin occurs in about 1 in 10^{10} through point mutations in the β-subunit of the *rpoB* RNA polymerase gene. As a result the rate of mutation needed to be resistant to both drugs would be $10^{-8} \times 10^{-10}$, or 10^{-18}. Since it is generally assumed that a tuberculosis cavity holds about 10^{12} microorganisms during disease, hundreds to thousands of resistant mutants will likely arise to each drug in any given patient, but it is extremely unlikely that a mutant will be resistant to both isoniazid and rifampin.

Combinations of antibiotics are effective in tuberculosis because of the independent and bactericidal mechanisms of action of the different antibiotics, the limited number of genetic sites that can confer resistance, and most importantly, because *M. tuberculosis* lacks the ability to share DNA with other bacteria. Efforts to prove that combinations of agents prevent the emergence of resistance in more common bacteria have generally failed in the clinical setting, mostly because of a combination of the mechanisms of resistance within a given strain and the acquisition of large segments of DNA (with multiple resistance determinants) from other bacteria.

Achieving Synergism in Antibacterial Activity

Three general types of synergism are achievable by combining more than one agent. The first is bactericidal synergism, in which either agent alone determines only bacteriostatic activity or negligible activity, but simultaneous exposure to two agents results in bacterial death. The primary example of such clinically relevant synergism is in the use of penicillins or vancomycin plus an aminoglycoside for the treatment of *E. faecalis* endocarditis (Chapters 61 and 270). In vitro, penicillins are static agents against most enterococci.

MICs for aminoglycoside exceed clinically achievable concentrations. When combined in vitro, the two agents synergize, thereby resulting in bacterial death (>99.9% kill). Unfortunately, the emergence and spread of aminoglycoside-modifying enzymes in enterococci, which yield high-level aminoglycoside resistance (MIC >2000 μg/mL), has limited the efficacy of these combinations by eliminating the synergism. More recently, combinations of ampicillin and ceftriaxone have shown efficacy against *E. faecalis* endocarditis. The mechanism for this synergism is not known, but is postulated to be inhibition of the full complement of *E. faecalis* penicillin-binding proteins. Given the prevalence of high-level aminoglycoside resistance and the more favorable toxicity profile of the double β-lactam combination, many centers have switched to ampicillin-ceftriaxone as first-line therapy for *E. faecalis* endocarditis (Chapters 61 and 270).

The second type of synergism is bacteriostatic synergism—combining two drugs to gain enhanced inhibitory activity against infecting strains. An example is the combination of trimethoprim and sulfamethoxazole, which inhibit sequential steps in the folate synthesis pathway, thereby resulting in combined activity that is greater than either antibiotic alone.

The third type of synergism uses a second agent to reverse a resistance phenotype. For example, β-lactamase inhibitors, most of which lack appreciable antibacterial activity against the target pathogens, can be combined with penicillins, cephalosporins, and carbapenems to enhance activity against many of our most resistant pathogens. In the United States, β-lactam-β-lactamase inhibitor combinations, such as ampicillin-sulbactam and piperacillin-tazobactam, are sold as fixed combinations and have become mainstays of treatment.

CONSIDERATIONS OF ANTIMICROBIAL ADMINISTRATION

ROUTE OF ADMINISTRATION

Antibiotics can be administered parenterally, orally, or locally. The chosen route depends upon the severity of the illness being treated, the characteristics of the antibiotic being administered, the ability to achieve sufficient concentrations of antibiotics at the site of infection, and, in some cases, social factors surrounding the treatment of an infection. For serious, life-threatening infections, the intravenous route is generally preferred, in part because of concerns about the reliability of gastrointestinal absorption under conditions of serious illness. Intravenous therapy facilitates achieving the peak and trough serum levels that are predicted based on body size and renal or hepatic function. The availability, safety, and durability of long peripherally inserted central catheters (PICC lines) and subcutaneous ports have facilitated long-term outpatient administration of intravenous antimicrobial agents,[7] thereby reducing hospital length of stay. Parenteral antimicrobials can also be administered by the intramuscular route, although the rapidity of absorption may be difficult to predict in patients who have a high body mass index or low blood pressure.

Oral therapy is preferred for less serious infections and for infections that require prolonged courses of treatment. Potent antimicrobial classes that have virtually 100% bioavailability when administered orally under normal circumstances include fluoroquinolones, doxycycline, metronidazole, and linezolid. Conversely, β-lactams have limited to poor oral absorption, and some antimicrobials, such as vancomycin and aminoglycosides, have very limited oral absorption. Because of this characteristic, vancomycin can be used as oral local therapy for colonic *Clostridioides difficile* infection (Chapter 271).

Antibiotics may be administered locally for a variety of reasons. Presurgical decontamination for methicillin-resistant *S. aureus* with mupirocin ointment to the nares can reduce infection after a sternotomy. Intraocular infections can be treated with direct injections into the vitreous because of the difficulty achieving appropriate concentrations with parenteral administration. Superficial eye infections are often treated with antibiotic ointments (Chapter 391). Superficial skin infections can be treated topically with combinations of agents that would be too toxic to administer by any systemic route. Treatment of peritoneal infections complicating peritoneal dialysis are often treated by incorporating sufficient concentrations of antibiotics into the peritoneal dialysis fluid.

Sometimes the route of administration is chosen based on social factors. Treatment of gonorrhea (Chapter 275), for example, often involves a single intramuscular dose of ceftriaxone, partly driven by the rates of resistance of *Neisseria gonorrhoeae* to oral agents but also by the desire to administer a single curative dose for patients who may not be reliable in completing oral tetracycline therapy, especially given the public health implications associated with continued transmission.

PHARMACODYNAMIC CONSIDERATIONS

Pharmacokinetics involves the absorption, distribution, and elimination of antibiotics in individuals of different ages, genders, and body types. The pharmacodynamics portion involves outcomes of treatment in in vitro settings to determine the extent to which inocula of bacteria are inhibited or killed, as well as the temporal parameters associated with optimal activity. These techniques can guide dosing intervals and blood level goals to maximize the efficacy and minimize the toxicity of antimicrobial therapy. For example, killing associated with ß-lactam agents best correlates with the percentage of time that the drug concentration is close to the minimum inhibitory concentration (time-dependent killing), whereas killing with fluoroquinolones and aminoglycosides is best associated with achieving a maximum concentration during the dosing interval (concentration-dependent killing); other antibiotics (e.g., vancomycin) kill best with a combination of high peak and prolonged duration (area-under-the-curve killing).

DURATION OF THERAPY

The emergence and spread of multiresistant and even pan-resistant bacterial strains have made apparent the need to reduce the selective pressure for resistance by reducing exposure to antibiotics. One component of this effort has been to examine the required duration of antimicrobial therapy for specific types of infections. More than 45 randomized controlled trials have compared the efficacy of shorter courses of antibiotics with traditional longer courses,[8] and, with very few exceptions, the shorter courses have been equally effective, whereas the longer courses have sometimes been associated with more adverse events. For example, community-acquired pneumonia can be treated for 3 to 5 days and ventilator-associated pneumonia for 7 to 8 days, compared with the traditional 14-day course (Chapter 85). Other types of infections for which shorter courses have been found to be safe and effective include streptococcal pharyngitis,[A3] exacerbation of bronchitis (Chapter 84),[A4] pneumonia,[A5] urinary tract infections (Chapter 263),[A6] skin and soft tissue infections, intra-abdominal infections, gram-negative bacteremia (Chapter 94), and neutropenic fever (Chapter 260). In the absence of surrogate markers to describe the state of the infection during treatment, such as the viral load in managing HIV infection (Chapter 357), a good general principle is that when infected patients look better and appear to have returned to baseline, they likely no longer need antibiotics.

One strategy to reduce the duration of antimicrobial exposure is the programmed variation in empirical antimicrobial usage within different areas of the hospital, most commonly in intensive care units (ICUs). This strategy has been referred to as antimicrobial cycling, or "crop rotation." The hope is that switching the most frequently used antibiotic from one agent to another after a specified period on a recurrent basis, with perhaps four different antibiotics (e.g., piperacillin-tazobactam for 3 months, cefepime for 3 months, imipenem for 3 months, ciprofloxacin for 3 months, then back to the piperacillin-tazobactam) will reduce the likelihood that local resistance will emerge to any one agent. Unfortunately, resistant bacteria from elsewhere in the hospital will often be introduced when patients are transferred into the ICU. Furthermore, different classes of antibiotics may promote resistance through the same mechanisms (e.g., selecting for overexpression of efflux pumps or β-lactamases), so resistance is unlikely to decline unless the overall usage of antibiotics declines.

ADMINISTRATIVE ASPECTS OF ANTIMICROBIAL THERAPY

ANTIMICROBIAL STEWARDSHIP

The problem of antimicrobial resistance is growing in the United States and worldwide[9,10] because of marked increase in their use,[11] and a postantibiotic world may be approaching in some geographic areas and for some medical conditions. Stewardship programs (Table 258-2) designed to improve adherence to recommended antimicrobial therapy (Chapter 261) have shown local success that offers hope for reducing or reversing some types of resistance.[A7–A10]

Stewardship programs are also important to control pharmaceutical costs, which account for the largest and fastest-growing segment of health care costs. Most hospitals control their spending on drugs by using formularies to define which drugs can be freely used by prescribing physicians, which drugs need special approval for use, and which drugs are not available because less expensive and equally effective, safe, and convenient alternatives are provided. It is critical that experts and pharmacists in infectious diseases advise these decisions so that cost is not the sole consideration when deciding among similar antibiotics.

The three components of successful strategies to address antimicrobial resistance are effective infection control measures, appropriate use of existing

TABLE 258-2 CORE ELEMENTS OF HOSPITAL ANTIMICROBIAL STEWARDSHIP PROGRAMS

Hospital Leadership Commitment: Dedicate necessary human, financial, and information technology resources
Accountability: Appoint a leader or co-leaders, such as a physician and pharmacist, responsible for program management and outcomes
Pharmacy Expertise: Appoint a pharmacist, ideally as the co-leader of the stewardship program, to lead implementation efforts to improve antibiotic use
Action: Implement interventions, such as prospective audit and feedback or preauthorization, to improve antibiotic use
Tracking: Monitor antibiotic prescribing, impact of interventions, and other important outcomes (e.g., *C. difficile* infection and resistance patterns)
Reporting: Regularly report information on antibiotic use and resistance to prescribers, pharmacists, nurses, and hospital leadership
Education: Educate prescribers, pharmacists, and nurses about adverse reactions to antibiotics, antibiotic resistance, and optimal prescribing

antimicrobial agents, and the development of new antimicrobials. In recent years, the U.S. Food and Drug Administration has approved a number of new antibacterial agents (Table 258-3), some of which are effective in treating multidrug-resistant bacteria. However, because of the substantial cost of these agents, their use has been largely restricted to documented cases of resistant infections.

259 APPROACH TO FEVER OR SUSPECTED INFECTION IN THE NORMAL HOST

MICHAEL T. MELIA

OVERVIEW OF FEVER

DEFINITION

The traditional definition of a normal temperature as 98.6° F (37.0° C) came from a study more than 150 years ago, when 98.6° F (37.0° C) was the mean temperature from over 1 million axillary temperature measurements in 25,000 patients. Multiple more recent studies show contemporary axillary temperatures to be lower, with a mean axillary temperature of 96.75° F (36° C)[1] and a mean oral temperature of about 36.5° C or 98° F.[2,3]

Human temperature also varies by time of day, with mean nadir temperatures in the early morning (i.e., 6 AM) and mean zenith temperatures in the

ABSTRACT

Fever is a sign in infectious and noninfectious illnesses that range from self-limited to life-threatening. Based upon data from young, healthy volunteers, a fever can be defined as a temperature greater than 99° F (37° C) at 6 AM or 100° F (37.8° C) any time of day. Many fevers are caused by processes that are either self-limited or readily diagnosed and treated. Some febrile syndromes, however, such as acute-onset fever and rash, fever in the returning traveler, and fever of unknown origin, have daunting and nearly limitless potential causes. For such scenarios, a thoughtful history must include information about exposures, travel, concurrent medical problems, medications, allergies, and vaccinations. A comprehensive physical examination is key. Diagnostic testing should be targeted toward conditions suggested by the history and physical examination so that diagnosis-specific therapy can be chosen.

KEYWORDS

fever
thermoregulation
fever and rash
fever of unknown origin

late afternoon and early evening (i.e., 4 to 6 PM). In one study of healthy volunteers, the maximum normal oral temperature, as defined by the 99th percentile, was 98.9° F (37.2° C) at 6 AM and 99.9° F (37.7° C) at 4 PM. By this definition, any temperature greater than 99° F (37.2° C) at 6 AM or 100° F (37.8° C) any time of day can be considered a fever.

Some studies have suggested that older individuals have lower mean temperatures than younger persons, but other studies have found that older persons' mean core temperatures are no different. Similarly, data in women as compared with men are inconsistent. Overall, any differences in normal mean temperatures by age and sex are negligible and not clinically significant.

EPIDEMIOLOGY

Most infections are transmitted from person to person to person by direct contact (e.g., hands, fomites), emanate from a common source (e.g., food, water), are spread by aerosols or respiratory droplets (e.g., viral respiratory infections), or are transmitted by vectors (e.g., mosquitos), often as zoonoses (Chapter 303). Infections also can be caused by breaches in skin integrity or self-injection. However, the source is often unknown. Risk factors therefore include contact with other sick individuals, exposure to contaminated food or water, proximity to animals, mosquito bites, and injection drug use (Chapter 365). Geographic exposures also vary, even in developed countries, where diseases such as histoplasmosis (Central and Eastern United States; Chapter 308), coccidioidomycosis (Southwestern United States; Chapter 308), Lyme disease (Chapter 296), babesiosis (Chapter 324), and ehrlichiosis (Chapter 302) are seen in certain geographic areas. Prior vaccination reduces the risk of many infections (Chapter 15), but immunity to many of those infections wanes over time.

PATHOBIOLOGY

Multiple temperature sensors throughout the body are thought to provide feedback via neural pathways to a dynamic federation of independent thermoeffector loops within the preoptic anterior hypothalamus. Each controller has its own threshold for signaling its effector to modulate the transfer of heat. These independent controllers and effectors work in a coordinated and, as appropriate, additive fashion to achieve the desired body temperature.[4]

The generation of fever involves exogenous pyrogens, of which bacterial endotoxin (lipopolysaccharide) from the outer membrane of gram-negative bacteria is a classic example, and endogenous pyrogens or pyrogenic cytokines. Exogenous pyrogens bind to pattern recognition receptors expressed by cells of the innate immune system. This binding triggers gene expression and synthesis of pyrogenic cytokines, such as interleukin (IL)-1, IL-6, tumor necrosis factor (TNF)-α, and interferon (IFN)-γ, as well as many other molecules fundamental to the febrile response. IL-6 is in turn integral to the production of many acute-phase reactants. The binding of lipopolysaccharide to pattern recognition receptors on pulmonary and hepatic macrophages also activates enzymes required for synthesis of prostaglandin E_2, which is critical to the generation of fever by its interaction with the thermoregulatory system. Medications such as nonsteroidal anti-inflammatory drugs and aspirin block the activity of enzymes involved in the synthesis of prostaglandin E_2.

When patients fail to develop a fever despite severe bacterial infection, morbidity and mortality tend to be higher. This phenomenon suggests that fever may either inhibit the multiplication of some pathogens or increase the entry of neutrophils into inflammatory sites.

CLINICAL MANIFESTATIONS

Fever is typically associated with relative or absolute tachycardia of about 2 to 5 beats per minute per 1° F increase in temperature. Temperature-pulse dissociation,[5] which is the absence of this response, is classically found in typhoid fever (Chapter 284), leptospirosis (Chapter 298), rickettsiosis (Chapter 302), dengue (Chapter 352), legionellosis (Chapter 290), and babesiosis (Chapter 324).

The peripheral vasodilation in response to fever contributes to the relative tachycardia and may blunt the increase in blood pressure that typically accompanies adrenergic activation. Relative or absolute hypotension can auger the development of septic shock (Chapter 94), which portends a poor prognosis.

The source of fever is often suggested by accompanying symptoms or signs, including headache or altered mental status in meningitis (Chapter 381) or encephalitis (Chapter 383), sore throat in pharyngitis (Chapter 397), ear pain in otitis (Chapter 394), upper respiratory symptoms in tracheitis (Chapter 84) or sinusitis (Chapter 394), cough and sputum in pneumonia (Chapter 85), abdominal pain in visceral abdominal infections (Chapters 128 and 141), diarrhea in enteric infections (Chapter 262), and pelvic pain in pelvic inflammatory disease (Chapter 264). However, localizing symptoms may be absent in infectious endocarditis (Chapter 61) and sepsis (Chapter 94). Elderly individuals and patients with diabetes mellitus are more likely to develop severe infections.

DIAGNOSIS

Just as there is no single definition of fever, there is no single approach to the evaluation of a febrile patient. An individualized approach is warranted. Most febrile patients have common, self-limited processes; some warrant further evaluation with laboratory testing and imaging, and a smaller subset have potentially serious or life-threatening conditions. A thoughtful history (including information about exposures, travel, concurrent medical problems, medications, allergies, and prior vaccinations) and a careful physical examination are always important.

Fever in Outpatients

When seeing a generally healthy febrile patient in the ambulatory setting, aggressive diagnosis may not be appropriate since the syndrome may resolve spontaneously with supportive care. For patients who appear toxic, tachypneic, or confused or have localized findings, however, blood cultures[6] and a prompt, targeted diagnostic evaluation[7] are indicated. For these sicker outpatients, molecular testing of body fluids is now a rapid way to diagnose worrisome respiratory or enteric infections. Urinalysis and urine culture are indicated for suspected urinary tract infection (Chapter 263), lumbar puncture for suspected meningitis (Chapter 381), blood culture for suspected sepsis (Chapters 61 and 94), microscopic evaluation or culture for suspected sexually transmitted diseases (Chapter 264), and aspiration or biopsy for liver infections (Chapter 137), septic arthritis, and osteomyelitis (Chapter 251).

The white blood cell count is usually elevated with a neutrophilic predominance (Chapter 153) in bacterial infections but may not be elevated in certain infections. Examples include some patients with typhoid fever or infections such as tuberculosis and histoplasmosis, which can involve the bone marrow, and patients who have overwhelming sepsis. Premature neutrophilic forms and a low serum bicarbonate level suggest severe infection. Viral infections are typically associated with a normal or only slightly elevated white blood cell count, typically with selective lymphocytosis.

Fever in Inpatients

Most hospital-associated fevers are nosocomial bacterial infections of the lower respiratory tract, urinary tract, or surgical wounds (Table 259-1). Leukocytosis is common and sometimes is the primary manifestation when fever is minimal in elderly patients or patients who are on fever-suppressing medications. Nosocomial fevers may lack obvious symptoms or signs, especially intra-abdominal processes such as acalculous cholecystitis (Chapter 141), bowel infarction (Chapter 129), viscus perforation, or abscesses (Chapter 128). Antibiotic-induced *Clostridioides difficile* (Chapter 271) can cause fever and a leukemoid reaction, even with little or no diarrhea. In hospitalized patients, drug fever (Chapter 234) is common, may be suggested by findings such as interstitial nephritis (Chapter 108) or elevated aminotransferase levels (Chapter 136), and requires withdrawal of potentially offending medications.

TABLE 259-1 MAJOR CAUSES OF HOSPITAL-ASSOCIATED FEVER

COMMON	LESS COMMON
INFECTIOUS	**INFECTIOUS**
Clostridioides difficile enterocolitis	Biliary tract disease
Pneumonia	Endometritis
Surgical wound	Intra-abdominal abscess
Urinary tract	Mediastinitis
Vascular catheter	Sinusitis
NONINFECTIOUS	**NONINFECTIOUS**
Drug-induced fever	Adrenal insufficiency
Hematoma	Gout
Immediate postoperative state	Myocardial infarction
Transfusion reaction	Organ infarction
Venous thromboembolism	Pancreatitis

From Leggett JE. Approach to fever or suspected infection in the normal host. In: Goldman L, Schafer A, eds. *Goldman-Cecil Medicine*, 26th ed. Philadelphia: Elsevier; 2020.

In severely ill patients, such as patients in intensive care units, about 80% of febrile episodes are caused by infectious processes, including pneumonia and infections related to indwelling catheters and devices. However, fever is also seen in the absence of infection after acute myocardial infarction (Chapter 58), deep vein thrombosis (Chapter 68), pulmonary embolism (Chapter 68), and ischemic or hemorrhagic stroke (Chapters 376 and 377). Fever and chills may also occur during or after transfusions of blood products (Chapter 162).

SPECIFIC FEVER SYNDROMES

FEVER AND RASH

The potential causes of fever with a rash include a long list of pathogens and processes. Diagnosis must begin with a systematic history and comprehensive physical examination (Chapter 6). The data thereby obtained can help prioritize a differential diagnosis and guide any further diagnostic testing.

History

When interviewing a patient who has fever and rash, the routine questions related to the history of present illness should be augmented by a specific set of inquiries:

- Does the patient have any known immunocompromising conditions?
- Has there been any known skin trauma or breakdown?
- Has the patient recently traveled domestically or internationally?
- Have there been any known animal contacts, including domestic as well as wild animals?
- Have there been any outdoor exposures, including to plants, gardening, spelunking, or possible arthropod bites?
- Have there been any notable ingestions, including raw seafood or undercooked meat?
- Has the patient had any water exposures, including swimming, fishing, hot tub use, or aquarium care?
- Has the patient had recent contact with anyone else known to be ill?
- Has the patient taken any new prescription or over-the-counter medications within the past 2 months?
- Does the patient have any known medication allergies?
- Has the patient had any new sex partners? Do they have any concerns regarding possible sexually transmitted infections?
- Has the patient engaged in injection drug use?
- Has the patient received all recommended childhood and adult vaccines?

Physical Examination

Understanding the nature and history of the patient's rash is also fundamental (Table 259-2). The following aspects should be ascertained by the physical examination and further focused questioning.

- What is the character of the rash?
  - Macule: flat, non-palpable lesions flush with the surface of the skin (see Fig. 406-1)
  - Papule: superficial, fleshy, palpable lesions raised above the surface of the skin (see Fig. 406-3)
  - Nodule: deeper, discrete, firm, raised lesions (see Fig. 407-22B)
  - Vesicle: fluid-filled lesion measuring ≤5 mm (see Fig. 403-10)
  - Bullae: fluid-filled lesions measuring >5 mm (see Fig. 406-11)
  - Pustule: raised lesion filled with pus (see Fig. 406-27)
  - Petechiae: pinpoint (<2 mm), non-blanching, red-brown, flat lesions (see Figs. 158-2 and 406-4)
  - Purpura: larger, non-blanching, red-brown, flat or raised lesions reflecting coalesced petechiae (see Fig. 406-5)
- What is the distribution of the lesions?
- Over what timeframe did the rash erupt and evolve as compared with the timing of onset of fever and additional signs or symptoms?
- How many lesions are there?
- In what way has the rash changed since its onset?
- Are the lesions localized to the skin (exanthem) or is there also a mucosal component (enanthem)?

In addition to the fever, a careful review of vital signs is essential because some causes of fever and rash are life-threatening. Other key aspects of the physical examination warranting attention include the presence or absence of pharyngitis or other mucosal lesions, adenopathy, hepatosplenomegaly, arthritis, and meningismus or an altered mental status.

Diagnosis

The type of skin finding and its distribution (especially to the palms or soles) can aid in the diagnosis. Syndromes of fever and rash range from self-limited skin infections to acute emergencies. Fever with a maculopapular rash in adults is seen especially in meningococcemia (Chapter 274), infectious mononucleosis (Chapter 348), West Nile virus (Chapter 352), Zika virus (Chapter 352), rubella (Chapter 339), primary human immunodeficiency virus (Chapter 355), parvovirus B19 (Chapter 342), Rocky Mountain spotted fever (Chapter 302), ehrlichiosis (Chapter 302), and exanthematous drug reactions (Chapter 234).[8]

Excluding Medical Emergencies

Neisseria meningitidis bacteremia (meningococcemia; Chapter 274) causes fulminant illness that can lead to death within days. Hemorrhagic skin lesions (Fig. 274-3) are its hallmark. In the context of sudden-onset fever and rapidly progressive septic shock with multisystem organ dysfunction, patients can initially manifest a maculopapular eruption, typically involving their extremities and trunk, before the lesions promptly evolve into petechiae and purpura fulminans. Generalized muscle tenderness is often seen, and digital gangrene is common. Although petechiae can arise in any patient with septic shock, their presence with or without purpura should prompt immediate antimicrobial therapy active against *N. meningitidis* (Chapter 274) as well as other potential pathogens, including *S. pneumoniae* (Chapter 268). Droplet precautions are warranted for *N. meningitidis*, and close contacts should receive antimicrobial prophylaxis.

Rickettsia rickettsii, the cause of Rocky Mountain spotted fever (Chapter 302), is a potentially fatal tick-transmitted infection. More than half of the cases of spotted fever rickettsioses reported in the United States occur in Arkansas, Missouri, North Carolina, Tennessee, and Virginia. Initial manifestations include fever and flulike symptoms, including headache, myalgia, and arthralgia. Rash typically is not present when the symptoms begin and is present only in about 50% of patients after 72 hours of illness, but nearly 90% of patients eventually erupt an initially maculopapular rash that evolves into petechial lesions (Fig. 302-2). The rash typically begins on the extremities and can involve the palms and soles; as it progresses, it can spread centripetally to the trunk.[9] Because of the delayed-onset rash, clinicians should maintain a high index of suspicion in appropriate epidemiologic circumstances.

Stevens-Johnson syndrome (Fig. 403-8) and toxic epidermal necrolysis (Fig. 407-5) reflect different ends of the spectrum of the same process (Chapter 407), with Stevens-Johnson syndrome involving up to 10% of total body surface, toxic epidermal necrolysis more than 30%, and 10 to 30% involvement reflecting overlap. These conditions are typically triggered by medications, including antimicrobial agents (Chapter 234). Clinical manifestations include an initial 1- to 3-day prodrome of fever, flulike symptoms, and a morbilliform rash or atypical targetoid macules followed by confluent, purpuric macules, sheets of denuded skin, and painful mucosal lesions. Untreated disease leads to widespread full-thickness epidermal necrosis and may progress to multisystem organ failure. Patients with toxic epidermal necrolysis are most appropriately managed in burn units (Chapter 97).

Although initially associated with tampon use in young menstruating women, toxic shock syndrome can follow any *Staphylococcus aureus* (Chapter 267) or *Streptococcus pyogenes* (Chapter 269) infection. Manifestations are abrupt in onset and include fever, severe myalgia, hypotension, diffuse erythema (Table 269-2), mucosal hyperemia, and multisystem organ failure. Skin desquamation follows 1 to 3 weeks after disease onset. Positive blood cultures are rare. Distinguishing Stevens-Johnson syndrome/toxic epidermal necrolysis from toxic shock syndrome, which can be accomplished by biopsy, is critically important, because the management of one commonly necessitates discontinuation of antibiotic therapy, whereas antibiotic use is essential in the other.

Necrotizing fasciitis (Chapters 97, 267, and 269) is a potentially lethal soft tissue infection triggered by antecedent cutaneous trauma. The majority of patients manifest superficial cutaneous signs, including soft tissue erythema and edema. Despite the prevalence of these findings, the hallmark of necrotizing fasciitis is pain out of proportion to findings in physical examination; a high clinical index of suspicion is warranted, because cutaneous and radiographic abnormalities can be limited or absent. Appropriate management includes immediate surgical debridement and antibiotic therapy.

Measles virus (Chapter 338) typically presents with high fever, cough, coryza, conjunctivitis, and an enanthem of small (1 to 3 mm), raised, white, grain-of-sand–like lesions on an erythematous base (Koplik spots; Fig. 338-2) within the oral (chiefly buccal) mucosa. This prodrome is followed by an erythematous maculopapular exanthem that starts over the face and spreads centrifugally to the periphery, potentially including the palms and soles (Table 259-3). The rash typically persists for 5 days, desquamates as it heals, and resolves in the sequence in which it arose. Potential complications include pneumonia and acute or chronic encephalitis.

TABLE 259-2 CAUSES OF FEVER AND RASH BY RASH MORPHOLOGY

RASH MORPHOLOGY	TREATABLE INFECTIOUS CAUSES	UNTREATABLE INFECTIOUS CAUSES	NONINFECTIOUS CAUSES
Petechial or purpuric	*C. canimorsus* Endocarditis Epidemic typhus (*R. prowazekii*) (severe) Gram-negative bacteria (purpura fulminans owing to sepsis) Hepatitis B *L. monocytogenes* *N. meningitidis* *N. gonorrhea* *P. falciparum* Rat bite fever Rocky mountain spotted fever (*R. rickettsii*) and other rickettsiae Scarlet fever (*S. pyogenes*) (Pastia lines) *S. aureus* *S. pneumoniae*	Adenovirus Cytomegalovirus Dengue virus Enteroviruses Epstein-Barr virus Rubella (soft palate) Variola Viral hemorrhagic fevers	Adverse drug reaction Amyloidosis Drug reaction with eosinophilia and systemic symptoms (DRESS) Henoch-Schoenlein purpura Cryoglobulinemic vasculitis Scurvy Small vessel vasculitis Systemic lupus erythematosus Thrombotic thrombocytopenic purpura

FEVER AND MUSCULOSKELETAL COMPLAINTS

Fever with localized musculoskeletal tenderness, swelling, or erythema suggests a local bacterial infection such as septic arthritis (Chapter 251), osteomyelitis (Chapter 251), or a spinal epidural abscess (Chapter 382). However, polyarthritis can also accompany disseminated gonococcal infection (Chapter 275), chikungunya (Chapter 352), dengue (Chapter 352), parvovirus B19 (Chapter 342), hepatitis B and C (Chapters 134 and 135), and Lyme disease (Chapter 296). Osteomyelitis of the vertebrae is almost always initiated by discitis with symmetrical involvement of vertical adjacent vertebrae. Myositis is seen in clostridial (Chapter 271), streptococcal (Chapter 269), or mixed aerobic-anaerobic infections. Myositis of deep muscles (e.g., the psoas or gluteus) is usually due to *S. aureus* (Chapter 267) in the United States but to *M. tuberculosis* (Chapter 299) in areas where tuberculosis is endemic. Leptospirosis (Chapter 298) and toxoplasmosis (Chapter 320) can cause diffuse myositis, and rhabdomyolysis (Chapter 99) can occur with legionellosis (Chapter 290) and a variety of viral infections.

POSTOPERATIVE FEVER

Significant infections within 24 hours after surgery (Chapter 401) are usually due to *S. pyogenes* (Chapter 269) or *Clostridium* species (Chapter 271). Urinary tract infections (Chapter 263) may be seen in patients who have undergone urologic instrumentation or who have had an indwelling catheter for 3 or more days. However, the presence of abnormalities on urinalysis or even a positive urine culture does not prove that the infection is the cause of fever, so a full diagnostic evaluation is mandatory. Wound infections causing fever are uncommon but typically occur about 5 to 7 days postoperatively and are more common after gastrointestinal procedures. Toxin-producing *C. difficile* (Chapter 271) is the only significant nosocomial postoperative gastrointestinal infection. Deep venous thrombosis or pulmonary embolism (Chapter 68) is rare except in patients who have not received appropriate prophylaxis. Fever without localizing signs is often drug-related (Chapter 234) but also can be caused by conditions such as atelectasis (Chapter 78) or acalculous cholecystitis (Chapter 141).

FEVER WITH LYMPHADENOPATHY, HEPATOSPLENOMEGALY, OR JAUNDICE

Fever with lymphadenopathy can be a manifestation of infectious and noninfectious (Table 259-4) illnesses. Generalized lymphadenopathy (Chapter 154) is seen with systemic infections, whereas focal lymphadenopathy is seen with local and systemic infections.

Fever with splenomegaly (Chapter 154) suggests either a systemic infection (e.g., Epstein-Barr virus [Chapter 348], malaria [Chapter 316], babesiosis [Chapter 324], granulomatous hepatitis with hepatomegaly, *M. tuberculosis* [Chapter 299], histoplasmosis [Chapter 308], *Bartonella* species [Chapter 291], *Brucella* species [Chapter 286], *Coxiella burnetii* [Chapter 302], visceral leishmaniasis [Chapter 319], and schistosomiasis [Chapter 326]) or a malignant neoplasm, especially lymphoma (Chapters 171 and 172). Fever with hepatomegaly or jaundice (Table 259-5) is sometimes seen with systemic infections that localize to the liver (e.g., leptospirosis), but it also suggests liver-specific pathology and is likely to be associated with elevated liver enzymes. However, liver enzymes can also be elevated in severe generalized bacterial infections in the absence of detectable anatomic liver disease or jaundice.

FEVER OF UNKNOWN ORIGIN

Most patients with acute fever have either a self-limited process or a problem that is promptly diagnosed. A subset, however, has persistent fevers despite an initial diagnostic evaluation. Such patients are described as having fever of unknown origin, generally defined as an illness of more than 3 weeks' duration,

HIV = human immunodeficiency virus.
Adapted from Wright WF, Auwaerter PG. Fever and fever of unknown origin: review, recent advances, and lingering dogma. *Open Forum Infect Dis*. 2020;7:ofaa132; Hersch EC, Oh RC. Prolonged febrile illness and fever of unknown origin in adults. *Am Fam Physician*. 2014;90:91-96.

fever >101° F on several occasions, and continued diagnostic uncertainty despite appropriate investigations, including at least three outpatient visits or at least 3 days in the hospital.[10]

Conditions that cause persistent fevers can be grouped into five domains: infections, inflammatory (i.e., rheumatologic or connective tissue diseases), malignant, miscellaneous, and undiagnosed (Fig. 259-1).[11,12] Each of these five broad domains encompasses many individual diagnoses, thereby suggesting a role for extensive testing. Before embarking on a detailed diagnostic evaluation of a patient with a fever of unknown origin, a general principle is that atypical presentations of common infectious diseases, such as tuberculosis (Chapter 299),[13] are more likely than is a common presentation of rare entities. Clinicians should be mindful of these common diagnoses (Table 259-6) when undertaking their initial comprehensive history and physical examination. If this initial evaluation yields potential diagnostic clues, these clues should help guide initial diagnostic testing (Table 259-7).[14] The addition of molecular testing has greatly increased the ability to detect pathogens in blood and other body fluids.[15,16]

When these core tests are unrevealing, 18F-fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET)/computed tomographic (CT) imaging can detect a cause in about 30 to 60% of cases.[17,18] FDG-PET/CT can itself be diagnostic (e.g., large-vessel vasculitis) or it can identify a metabolically active focus amenable to biopsy. Tissue biopsy of a lymph node, liver, bone marrow, or temporal artery can be guided by FDG-PET/CT or other test result.

Although empiric therapy is warranted for critically ill patients, completion of the diagnostic evaluation is otherwise preferred prior to empiric treatment to avoid masking or incompletely treating the underlying disorder. If no diagnosis is reached after completion of the diagnostic evaluation, consideration should be given to screening for autoinflammatory conditions (Chapter 240)[19,20] under the guidance of expert consultation. One option is continued watchful waiting, with periodic repeat evaluations. Another option is a trial of anti-inflammatory therapy (e.g., nonsteroidal anti-inflammatory drugs or systemic corticosteroids) based upon shared decision making with the patient.

TABLE 259-7 INITIAL DIAGNOSTIC EVALUATION FOR A PATIENT WITH FEVER OF UNKNOWN ORIGIN*

- Complete blood cell counts with white blood cell differential
- Comprehensive metabolic profile
- Urinalysis with sediment
- Erythrocyte sedimentation rate
- C-reactive protein
- Blood culture (three cultures, with at least two spaced over at least 24 hours)
- HIV Ag/Ab assay (fourth-generation)
- Cytomegalovirus (CMV) IgM and IgG
- Heterophile antibody
- *M. tuberculosis* interferon gamma release assay
- Ferritin
- Lactate dehydrogenase
- Thyroid-stimulating hormone
- Rheumatoid factor
- Antinuclear antibodies
- Chest radiograph
- Hepatitis A, B, and E serologies (if liver enzymes abnormal)
- Lower extremity compression ultrasonography with Doppler (if above nondiagnostic)
- Transthoracic echocardiography (if above nondiagnostic)
- Computed tomographic scan of chest, abdomen, and pelvis (if above nondiagnostic)

*Depending upon information gathered from the history and physical examination.
Ab = antibody; Ag = antigen; HIV = human immunodeficiency virus; Ig = immunoglobulin.

A comprehensive evidence-based approach to fever of unknown origin. *Arch Intern Med*. 2003;163:545-551.

SEVERE HYPERPYREXIA

Intrinsic thermoregulatory mechanisms almost always prevent fevers from exceeding 41° C (106° F). Temperatures above this level are usually due to central nervous system hemorrhage. Hyperthermia, whereby exogenous (e.g., prolonged exposure to high ambient temperatures) or endogenous (e.g., medications) mechanisms result in temperature elevations in the setting of unchanged thermoregulatory centers, can be difficult to distinguish from fever. In addition to medication-associated hyperthermia, other causes of hyperthermia include malignant hyperthermia (Chapter 400), heat stroke (Chapter 95), and the thermoregulatory dysfunction seen in patients with Parkinson disease (Chapter 378).

TREATMENT

Outpatient Ambulatory Setting

Most acute, undifferentiated febrile illnesses resolve spontaneously within 1 or 2 weeks without a specific diagnosis or therapy. In other cases, diagnostic clues from the history and physical examination and targeted basic tests (e.g., complete blood count, urinalysis, chest radiography) usually can guide therapy. In patients who have only nonspecific symptoms, watchful waiting with repeat evaluation by phone or in person may be sufficient. For more severe or prolonged symptoms, without localizing signs, an in-person physical examination, routine laboratory testing (e.g., a white blood cell count, metabolic profile, blood culture), and additional testing as suggested by the patient's history and epidemiologic risk factors may help guide therapy.

Empiric antibiotics should be avoided. Most pharyngitis (Chapter 397) in adults is viral, but streptococcal infection (Chapter 269) should be considered in patients who have tonsillar exudates, tender anterior cervical lymph nodes, and no cough. In such patients, a rapid streptococcal antigen test is indicated, with a positive test result prompting antibiotic treatment. Normal vital signs and a normal chest examination effectively exclude bacterial pneumonia, and antibiotics are of little, if any, value for nonspecific bronchitis (Chapter 84) or sinusitis (Chapter 394). By comparison, community-acquired pneumonia requires antibiotic therapy and often hospitalization (Chapter 85). Procalcitonin, which is an acute-phase reactant, is more likely to be elevated with bacterial than with viral infections, and procalcitonin-guided therapy can sometimes reduce unnecessary antibiotics, such as in respiratory infections,[A1] although it cannot be used in isolation to make decisions.[21] Furthermore, procalcitonin-guided therapy may not improve care in hospitals with high-quality care,[A2] in part because it poorly discriminates sepsis[A3] from nonseptic systemic inflammation. Prolonged fever and cough, which can be caused by *Bordetella pertussis* (Chapter 289), *Mycoplasma pneumoniae* (Chapter 293), and *Chlamydophila pneumoniae* (Chapter 294), should prompt a chest radiograph, molecular testing, and appropriate antibiotic treatment. For other localized infections, specific treatment is outlined in disease-specific chapters.

SUSPECTED NOSOCOMIAL INFECTION

In hospitalized patients, the history and physical examination remain the foundation of the evaluation of a patient with new-onset fever. Further diagnostic testing should be guided by these findings. Interpretation of culture data must consider the possibility of colonization, as occurs frequently in the lungs of intubated patients or in the urine of patients with indwelling urinary bladder catheters, from true infection (Chapter 261). Treatment, as outlined in disease-specific chapters, typically is guided by culture results.

FEVER IN THE RETURNING TRAVELER

Fever in the returning traveler is reviewed in Chapter 265.

APPROACH TO FEVER AND SUSPECTED INFECTION IN THE IMMUNOCOMPROMISED HOST

COSTI D. SIFRI

DEFINITION

Healthy individuals possess robust antimicrobial defense systems that include physical barriers in the form of skin and mucosal membranes, innate immune defenses that are conserved through evolution, and adaptive ("acquired") immune defense systems (Chapter 35). These systems, which are highly interconnected, work in concert through an array of defensive surfaces, cells, and soluble factors to protect a host from potential microbial assailants. The normal commensal microflora of the skin and mucosa protect the host by occupying body surface niches without activating the immune system and play an important role in the maturation and homeostasis of the immune system. Nutritional status, multiorgan function, and age all contribute to normal immune function. Damage to any of these host defense components increases the risk for infection. A wide assortment of conditions, including body surface burns (Chapter 97), endocrine and metabolic disorders, and medications such as glucocorticoids, can affect components of these defense systems and place an individual at increased risk for infection. In most patients, however, a compromised immune system is due to treatment of neoplastic disease (with particular attention to hematologic disorders such as leukemia and lymphoma), recipients of solid organ or stem cell transplants, and patients who are taking immunomodulatory medications for diagnoses such as collagen vascular and rheumatologic conditions. Management of people with acquired immunodeficiency syndrome (AIDS) is discussed in Chapters 357 and 358, and a more thorough discussion of primary immunodeficiency is provided in Chapter 231.

GENERAL CONCEPTS

The innate immune system serves as the first line of host defense (Table 260-1). Components of the innate immune system (Chapter 35) include natural physical and chemical barriers, phagocytic cells, and germline-encoded signaling systems that recognize molecular components unique to microbes that are invariant because they are essential for survival of the microbe. These signaling systems rapidly (minutes to hours) distinguish "nonself" from "self," thereby leading to the activation of protective phagocytic cells, proteolytic enzyme cascades, antimicrobial peptides, and other products. The innate immune system also primes the adaptive immune system, which is distinguished by the ability to create pathogen-specific responses and immunologic memory over several days. Like the innate immune system, the adaptive immune system is composed of both cellular and soluble factors (Chapter 35).

The risk for infection depends on the specific type of defect in host defenses. For example, impaired macrophage function as a consequence of tumor necrosis factor (TNF)–directed therapy is a predisposing risk for infection due to intracellular pathogens such as *Mycobacterium tuberculosis* (Chapter 299) and *Histoplasma capsulatum* (Chapter 308), whereas splenectomy and functional asplenism (Chapter 154) predispose to sepsis due to encapsulated bacteria, including pneumococcus (Chapter 268) and meningococcus (Chapter 274). Detailed understanding of the nature of compromised host defense mechanisms and how the defect influences susceptibility to potential viral, bacterial, fungal, or parasitic pathogens can guide appropriate diagnostic evaluations, therapies, and prevention strategies (through vaccination, antimicrobial prophylaxis, pre-emptive monitoring, and lifestyle changes).

Determining whether an immunocompromised individual has a clinically significant infectious disease can be challenging. Several factors make it more difficult to identify infectious disease in individuals with compromised immune defenses. Potential causes of infection are diverse and range from typical, community-acquired pathogens to less common, opportunistic pathogens. Signs of inflammation, including fever, pain, and erythema, may be reduced. Laboratory markers of infection, such as changes in the white blood cell count and hepatic transaminase levels, may be subtle or difficult to interpret owing to the influence of baseline noninfectious processes (e.g., medications, organ dysfunction). Radiographic findings may also be blunted. Accordingly, infection

APPROACH TO FEVER AND SUSPECTED INFECTION IN THE IMMUNOCOMPROMISED HOST

COSTI D. SIFRI

DEFINITION

Healthy individuals possess robust antimicrobial defense systems that include physical barriers in the form of skin and mucosal membranes, innate immune defenses that are conserved through evolution, and adaptive ("acquired") immune defense systems (Chapter 35). These systems, which are highly interconnected, work in concert through an array of defensive surfaces, cells, and soluble factors to protect a host from potential microbial assailants. The normal commensal microflora of the skin and mucosa protect the host by occupying body surface niches without activating the immune system and play an important role in the maturation and homeostasis of the immune system. Nutritional status, multiorgan function, and age all contribute to normal immune function. Damage to any of these host defense components increases the risk for infection. A wide assortment of conditions, including body surface burns (Chapter 97), endocrine and metabolic disorders, and medications such as glucocorticoids, can affect components of these defense systems and place an individual at increased risk for infection. In most patients, however, a compromised immune system is due to treatment of neoplastic disease (with particular attention to hematologic disorders such as leukemia and lymphoma), recipients of solid organ or stem cell transplants, and patients who are taking immunomodulatory medications for diagnoses such as collagen vascular and rheumatologic conditions. Management of people with acquired immunodeficiency syndrome (AIDS) is discussed in Chapters 357 and 358, and a more thorough discussion of primary immunodeficiency is provided in Chapter 231.

GENERAL CONCEPTS

The innate immune system serves as the first line of host defense (Table 260-1). Components of the innate immune system (Chapter 35) include natural physical and chemical barriers, phagocytic cells, and germline-encoded signaling systems that recognize molecular components unique to microbes that are invariant because they are essential for survival of the microbe. These signaling systems rapidly (minutes to hours) distinguish "nonself" from "self," thereby leading to the activation of protective phagocytic cells, proteolytic enzyme cascades, antimicrobial peptides, and other products. The innate immune system also primes the adaptive immune system, which is distinguished by the ability to create pathogen-specific responses and immunologic memory over several days. Like the innate immune system, the adaptive immune system is composed of both cellular and soluble factors (Chapter 35).

The risk for infection depends on the specific type of defect in host defenses. For example, impaired macrophage function as a consequence of tumor necrosis factor (TNF)–directed therapy is a predisposing risk for infection due to intracellular pathogens such as *Mycobacterium tuberculosis* (Chapter 299) and *Histoplasma capsulatum* (Chapter 308), whereas splenectomy and functional asplenism (Chapter 154) predispose to sepsis due to encapsulated bacteria, including pneumococcus (Chapter 268) and meningococcus (Chapter 274). Detailed understanding of the nature of compromised host defense mechanisms and how the defect influences susceptibility to potential viral, bacterial, fungal, or parasitic pathogens can guide appropriate diagnostic evaluations, therapies, and prevention strategies (through vaccination, antimicrobial prophylaxis, pre-emptive monitoring, and lifestyle changes).

Determining whether an immunocompromised individual has a clinically significant infectious disease can be challenging. Several factors make it more difficult to identify infectious disease in individuals with compromised immune defenses. Potential causes of infection are diverse and range from typical, community-acquired pathogens to less common, opportunistic pathogens. Signs of inflammation, including fever, pain, and erythema, may be reduced. Laboratory markers of infection, such as changes in the white blood cell count and hepatic transaminase levels, may be subtle or difficult to interpret owing to the influence of baseline noninfectious processes (e.g., medications, organ dysfunction). Radiographic findings may also be blunted. Accordingly, infection

ABSTRACT

The approach to suspected infection and fever in immunocompromised hosts differs from the approach in a normal host, both in terms of the potential pathogens as well as the clinical course. Examples include treatment of fever or suspected infection in patients with neoplastic diseases (particularly hematologic disorders such as leukemia and lymphoma), organ transplantation, and collagen vascular or autoimmune diseases.

TABLE 260-1 COMPONENTS OF THE IMMUNE SYSTEM

INNATE IMMUNE SYSTEM (IMMEDIATE, NONPATHOGEN-SPECIFIC, EVOLUTIONARILY ANCIENT, NO MEMORY)	
Physical defense mechanisms	Skin Mucous membranes (e.g., oral mucosa, olfactory mucosa, gastric mucosa, intestinal mucosa, bronchial mucosa, genitourinary mucosa) Tears Mucus Ciliated respiratory epithelium Urine flow
Innate soluble and cellular defense mechanisms	Stomach acid Complement system Phagocytes (i.e., neutrophils, macrophages, dendritic cells) C-type lectin receptors, toll-like receptors, NOD-like receptors, intracellular nucleic acid sensors Cytokines (e.g., IL-1, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, G-CSF, TNF-α, IFN-γ) Natural antimicrobial products (e.g., defensins, lactoferrin, lysozyme, reactive oxygen species) Neutrophil extracellular traps
ADAPTIVE IMMUNE SYSTEM (DELAYED, PATHOGEN-SPECIFIC, EVOLUTIONARY ORIGIN WITH JAWED VERTEBRATES [~0.5 BILLION YEARS], MEMORY)	
Cellular adaptive immune system	T lymphocytes • $CD8^+$ (cytotoxic) • $CD4^+$ (helper) • Γδ (alternative TCRs) • Treg (regulatory)
Humoral adaptive immune system	B lymphocytes • Immunoglobulins (IgM, IgG, IgA, IgE, IgD antibodies)
EFFECTORS OF IMMUNE FUNCTION	
Effector	Resident microbial flora Organ function Age Stress Nutrition Metabolic homeostasis (e.g., pH, iron, uremia)

G-CSF = granulocyte colony-stimulating factor; IFN-γ = interferon-γ; IL = interleukin; NOD = nucleotide oligomerization domain; TCR = T-cell receptor; TNF-α = tumor necrosis factor-α.

may be advanced at the time of presentation. Furthermore, multiple infections or processes may occur simultaneously. Diagnosis can be challenging because serologic testing may not be useful. However, recent advances in the development and adoption of molecular diagnostic assays have proved especially useful tools in immunocompromised patients. Finally, numerous noninfectious causes of fever, including neoplastic disease, collagen vascular disease, allograft rejection, graft-versus-host disease, and medications (e.g., antibiotic-induced fever, cytokine release syndromes following monoclonal antibody therapies) may cause febrile illnesses that are indistinguishable from infectious processes. Consequently, significant and expedited efforts should be made to establish the cause of fevers in a compromised host. Invasive procedures, such as imaging-guided biopsy, endoscopic procedures, and surgery, may be required to establish a diagnosis.

APPROACH TO THE PATIENT

Broadly speaking, the factors that predispose immunocompromised patients to infection can be divided into two categories: intrinsic host factors as a consequence of illness and factors associated with medical treatment. Intrinsic host factors include underlying immunodeficiencies, medical comorbidities, past infections, metabolic derangements, and poor nutritional status. For patients with cancer, mechanical obstruction from tumors can predispose to organ dysfunction, infection, and the formation of abscesses. Tumors of the head and neck, respiratory tract, gastrointestinal tract, and female genitourinary tract predispose to infections in and adjacent to those anatomic spaces. Patients with chronic progressive organ dysfunction and failure are predisposed to infection as a consequence of their illness. Structural lung problems, such as cavitary lung disease, increase the risk for colonization and superinfection by *Aspergillus* (Chapter 311) and nontuberculous mycobacteria (Chapter 300). Progressive respiratory failure predisposes persons to pneumonia due to community-associated, health care–associated, and opportunistic pathogens (Chapter 85). Progressive liver failure predisposes to fungal infections, including cryptococcosis (Chapter 309). Immunodeficiency as a direct consequence of acquired immune system disorders, such as hematologic malignancies or bone marrow infiltration by metastasis of solid tumors, adds another layer of risk of infection.

Medical treatment is the other major consideration that influences the risk for infection. Radiation therapy and cytotoxic chemotherapy of malignant disease directly or indirectly target cells of the immune system, thereby leading to significant risk for infection. Physical and natural barriers, such as skin, mucosal membranes, uroepithelium, and ciliated respiratory epithelium, may be injured or impaired as a consequence of disease or treatment. Surgery and medical devices, such as central venous catheters, indwelling urinary catheters, and circulatory support devices, among others, predispose to infections from a range of nosocomial pathogens, including *Staphylococcus aureus*, coagulase-negative staphylococci, enterococci, enteric gram-negative bacteria, *Pseudomonas aeruginosa*, other multidrug-resistant gram-negative bacteria, and *Candida*. Bleeding and fluid collections, such as urinomas and bilomas, may become seeded and infected after surgery. Repeated surgery is a risk for both organ transplant recipients and patients with solid tumors. Patients with primary or metastatic lung cancer are susceptible to recurrent pneumonia. Patients with head and neck cancer and brain cancer are predisposed to aspiration pneumonitis and pneumonia. The use of immunosuppressive medications following allogeneic stem cell or organ transplantation is a significant risk factor. The consequences of prior infections, empirical antibiotics, and treatment of infections lead to unbalanced changes in the composition of the gastrointestinal microbiome (termed *dysbiosis*) that may reduce barriers to colonization with drug-resistant pathogens and increase the risk of chemical infection.

The approach to the immunosuppressed patient requires detailed information about the nature of the immunodeficiency and known related risks. Specific immune defects in host responses are associated with specific underlying conditions and medical interactions (Table 260-2).

Patients with Neoplastic Disease

In patients with malignancies, the underlying condition contributes importantly to determining infectious risks. For example, absolute neutropenia or leukocyte dysfunction (Chapter 153) occurs in the setting of specific malignancies (e.g., acute or chronic leukemias). In such cases, the risk for bacterial infections is enhanced, even in the absence of chemotherapy. In other underlying conditions, such as chronic lymphocytic leukemia, patients frequently have quantitative defects in humoral host defense products, such as decreased immunoglobulins and components of the complement system, that are bactericidal. Other types of phagocytic cells include circulating monocytes and tissue macrophages, which are the fixed mononuclear cells of the reticuloendothelial system. These cells normally collaborate with helper T lymphocytes in defense against intracellular pathogens, such as mycobacteria, fungi, and some viruses and parasites. The spectrum of infectious risks is further broadened and prolonged when patients with these underlying immune defects are treated with cytotoxic drugs. Chemotherapies can also be deleterious to the function of other organs that are critical to host defenses, especially the integrity of the gastrointestinal tract's mucosal barrier and the airway's innate clearance mechanisms, thereby posing additional susceptibilities to bacterial and fungal pathogens. As a result, the underlying malignancy itself and the specific therapies that are used to treat it combine to create the profile of the types of infections to which the patient is at risk, both acutely and chronically.

Chimeric antigen receptor-modified T (CAR-T) cells and immune checkpoint inhibitors (Chapter 29), which are potent new classes of immunotherapeutics for cancer,[1] can cause severe immune-related adverse effects. CAR T-cell therapy causes cytokine-release syndrome and neurologic toxic effects, including encephalopathy. Immune checkpoint inhibitors' immune-related adverse effects can range from mild skin findings to significant inflammatory tissue injury, including colitis, hepatitis, and pneumonitis. Checkpoint blockade may also worsen pre-existing infection and even unmask subclinical infection as a consequence of enhanced immunologic function. Treatment of these immune-related adverse effects with immunomodulators such as glucocorticoids or interleukin-6 inhibitors may paradoxically increase the risk of infection.

Hematopoietic Stem Cell and Solid Organ Transplant Recipients

Hematopoietic stem cell transplantation (Chapter 163) exposes recipients to additional risks as a result of the agents used for conditioning therapy in preparation for the stem cell transplantation, variable rate and magnitude of

TABLE 260-2 CONDITIONS, INTERVENTIONS, AND IMMUNE DEFECTS TYPICALLY ENCOUNTERED IN COMPROMISED HOSTS

UNDERLYING CONDITION	INTERVENTION	TYPE OF DEFECT
Treatment of neoplastic diseases (particularly hematologic malignant neoplasms)	Underlying disease (without intervention)	Defects in production of bone marrow cells associated with defects in cellular immunity and phagocytic function (e.g., cytopenias associated with bone marrow infiltration with malignant cells)
	Cytotoxic chemotherapies	Bone marrow suppression; defects in primary and secondary humoral and cellular immunity; breach in mucosal barriers (skin, gut); impairment in mucociliary clearance; defects in other organ function (e.g., kidney, liver)
	Small molecule–targeted therapies (e.g., Bruton tyrosine kinase inhibitors, mTOR inhibitors)	Neutropenia, impaired cellular immunity
Hematopoietic stem cell transplantation	Underlying disease, without intervention (e.g., hematologic malignant neoplasms)	Defects in primary and secondary humoral and cellular immunity; defects in phagocytic cell quantity and function
	Cytotoxic conditioning therapy (± total body irradiation)	Bone marrow suppression; defects in primary and secondary humoral and cellular immunity; breach in mucosal barriers; defects in organ function
	Stem cell manipulation (e.g., T-cell depletion)	Delay in cellular engraftment
	Prophylaxis and treatment of graft-versus-host disease (e.g., glucocorticoids, calcineurin inhibitors, antimetabolites, TNF-α antagonists)	Defective function in phagocytic cells and dysfunction of primary and secondary humoral and cellular immunity
Solid organ transplantation	Underlying disease, without intervention (e.g., diabetes, end-stage liver disease)	Organ dysfunction and miscellaneous immune dysfunction
	Induction therapies (e.g., antilymphocyte globulin, anti–interleukin-2 Ab, anti-CD52 Ab)	Depletion and impairment in primary and secondary cellular and humoral immunity
	Surgical intervention and altered anatomy	Breach in mucosal barriers; defects in organ function
	Acute and chronic rejection prophylaxis and treatment (e.g., glucocorticoids, calcineurin inhibitors, antimetabolites and alkylating agents, plasmapheresis, antithymocyte globulin, monoclonal antibodies to B and T cells, anticytokine therapies, T-cell costimulation blockers)	Defective function in phagocytic cells, primary and secondary humoral and cellular immunity
Treatment of collagen vascular and autoimmune diseases	Anti-inflammatory and immunosuppressive agents (glucocorticoids, nonsteroidal anti-inflammatory drugs, calcineurin inhibitors, sirolimus, mycophenolate mofetil)	Defective function in phagocytic cells, primary and secondary humoral and cellular immunity
	Antimetabolite and alkylating agents	Bone marrow suppression, defects in primary and secondary humoral and cellular immunity
	Biologic immune response modifiers (e.g., antithymocyte globulin, monoclonal antibodies to B and T cells, anticytokine therapies, T-cell costimulation blockers)	Defective function in primary and secondary humoral and cellular immunity

Ab = antibody; mTOR = mechanistic target of rapamycin; TNF-α = tumor necrosis factor-α.

cellular engraftment, and, in recipients of allogeneic stem cell transplants, administration of additional agents to reduce risks for graft-versus-host disease (GVHD). GVHD itself and the treatments used to modulate it create additional risk for infection. Organ dysfunction, loss of natural barriers (skin and gut), and neutropenia enhance early risks for infection with bacteria and fungi that inhabit the gastrointestinal tract; impaired humoral and secondary immunity enhance late risks for infections caused by viruses, fungi, and encapsulated bacteria, especially in people who are treated aggressively for GVHD.

Immunodeficiency in solid organ transplant recipients is a consequence of the initiation and chronic maintenance of immunosuppressive therapies to suppress T- and B-lymphocyte function, so as to reduce risks for early and late graft rejection (Chapter 38). Additional factors that can exacerbate overall risks for infection include the altered anatomy preoperatively and postoperatively, the surgical intervention itself, and the potential of infection transmitted from the graft itself (i.e., donor-derived infection).

Transplant recipients have increased risks both for acute infection and for reactivation of latent infections after initiation of immunosuppression. Hence, pretransplantation evaluation should be focused on detection of latent herpesviruses (e.g., cytomegalovirus [CMV]) and other pathogens (e.g., *M. tuberculosis*) that can be transferred or reactivated with transplantation and immunosuppression.

The overall risk for infection in organ transplant recipients is determined by interactions between the patient's epidemiologic exposure and "net state of immunosuppression." Epidemiologic exposure to viral infections (both reactivation and disease) enhance risks for other infections. For example, cytomegalovirus infection (Chapter 347) is known to be a risk for additional infections by other microorganisms in recipients of both hematopoietic stem cell and solid organ transplant grafts. The "net state of immunosuppression" is a conceptual measure of all factors contributing to an individual patient's risk for infection at any given time (Table 260-3). Factors that influence the net state of immunosuppression[2] include underlying medical conditions (e.g., diabetes mellitus, advanced age, malnutrition), the use of specific immunosuppressive therapies (and their potential synergisms), technical problems during surgery, post-transplantation organ dysfunction, the administration of broad-spectrum antibiotics, and prolonged airway intubation or use of urinary and vascular access devices. This concept, which originated from an understanding of solid organ transplantation, can be applied to the care of all immunosuppressed patients.

TABLE 260-3 FACTORS CONTRIBUTING TO THE "NET STATE OF IMMUNOSUPPRESSION"

Immunosuppressive therapy: type, temporal sequence, and intensity
Prior and current therapies (chemotherapy, radiation therapy, antimicrobial agents)
Integument barrier integrity (e.g., catheters, lines, drains)
Neutropenia, lymphopenia, hypogammaglobulinemia
Underlying immune defects (e.g., autoimmune disease, genetic polymorphisms)
Metabolic conditions: uremia, malnutrition, diabetes, cirrhosis, advanced age
Viral infection (e.g., herpesviruses [CMV, EBV], HBV, HCV, HIV, RSV, influenza)

CMV = cytomegalovirus; EBV = Epstein-Barr virus; HBV = hepatitis B virus; HCV = hepatitis C virus; HIV = human immunodeficiency virus; RSV = respiratory syncytial virus.
Adapted from Fishman JA. Infection in organ transplantation. *Am J Transplant*. 2017;17:856-879.

An ever-increasing number of types of immunosuppressive therapies are frequently administered to patients with active connective tissue diseases and autoimmune conditions (Table 260-2). This population of patients is growing in importance with increasing use of biologic immune response modifiers (Chapters 28 and 29) that enhance risks for both reactivation of latent infection (e.g., *M. tuberculosis* and *H. capsulatum*) and severe manifestations of acute infection. Infectious risks should be considered in balancing need for these therapies and designing preventive regimens.

FEVER IN THE COMPROMISED HOST

The onset of fever in an immunocompromised patient can be an ominous development. Depending on the nature and magnitude of the impaired host defenses, including comorbid conditions, a febrile response can indicate the

onset of a life-threatening systemic infection. A diagnostic approach should be derived by careful consideration of the patient's signs and symptoms of infection, exact form(s) of immunocompromise, and whether the patient is at heightened risk for reactivation of latent infection. Because infection can progress rapidly, particularly in patients with absolute neutropenia (see later), empirical antimicrobial therapy is often indicated even before an infection is definitively identified.

In the setting of disease-associated or chemotherapy-induced neutropenia, fever is typically an important and often the only clinical indication of infection. Some patients with neutropenia and serious infection, especially patients who are elderly, may be afebrile or even hypothermic on presentation. The risk for bacterial infection increases proportionally with the decline in neutrophil count, especially with prolonged durations of significant neutropenia (Chapter 153). Infection rates increase with neutrophil levels below 1000 cells/μL and progressively increase as counts decline to less than 100 cells/μL. The duration of significant neutropenia is also an important determinant of the type of infection most likely to occur, with the risk for bacterial and fungal infections increasing with each successive week in which leukocyte counts are less than 500 cells/μL.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The presentation of a febrile, neutropenic patient should immediately prompt a systematic approach (Table 260-4). The differential diagnosis of fever should be influenced by local and hospital exposures as well as the type of preventive antibiotics the patient might be receiving and whether they likely altered the composition of the gastrointestinal microbiome. For example, the most common causes of fever during neutropenia are gram-negative bacteria, usually originating in the gastrointestinal tract, in the absence of the use of prophylactic and empirical antibiotics that cover them (especially quinolones and extended-spectrum β-lactams). By comparison, gram-positive bacteria are more likely in pretreated ambulatory patients, and drug-resistant gram-negative species (Chapters 282 and 283) are more common in hospitalized patients.

The type and duration of immunodeficiency (i.e., the "net state of immunosuppression") also can alter overall risk. Specific organ dysfunction, such as underlying pulmonary disease or renal impairment, can predispose to unique infectious syndromes (see later). Epidemiologic exposures should be thoroughly explored. Current and previously administered antimicrobial drugs affect risks for specific infections. For patients who are hospitalized in an acute care or chronic care facility or were recently hospitalized, it is particularly useful to have information on colonizing organisms that may display complex resistance profiles, such as vancomycin-resistant enterococci and bacteria that express extended-spectrum β-lactamases or other resistance determinants (e.g., carbapenemases). Knowledge of recent colonization with these organisms or local institutional epidemiology should be considered when tailoring initial antibiotic management.

The onset of fever in a patient who is neutropenic or otherwise immunocompromised requires a prompt and thorough bedside evaluation. Severely neutropenic patients may not be able to mobilize a sufficient number of leukocytes to develop a clinically apparent inflammatory response. For example, they may not exhibit the expected brisk peritoneal signs of an acute abdomen, meningeal signs of a central nervous system (CNS) infection, or localized tenderness, swelling, and erythema for an abscess. Beginning with examination of the head and neck, there should be a specific examination for evidence of CNS infection as well as a general evaluation of mental status. The oropharynx must be examined for evidence of pharyngitis and focal tenderness. Sinus membranes should be evaluated for the presence of erythema or necrosis. Complete examination of the heart, lung fields, and abdomen is critical, with attention to the potential presence of new murmurs, abnormal breath sounds, and intra-abdominal tenderness. The entire integument, including the perirectal area, should be examined, because severely neutropenic patients tend to get infections at either end of the gastrointestinal tract. Intravenous catheter exit sites and tunnels should be carefully inspected, and blood should be drawn through catheters for culture. Because classic signs of infection of catheter exit sites and tunnels can be absent or blunted in patients with neutropenia (with signs of infection present only after recovery of neutrophils), examination should be performed daily and with close scrutiny for evolving localized infection that may necessitate catheter removal.

Laboratory studies should emphasize tests that can yield prompt results, such as Gram stain or polymerase chain reaction (PCR) testing of body fluids, exudates, or aspirates. Blood cultures and cultures of other body fluids should be obtained promptly, preferably before initiating empirical antibiotics. Routine blood work should include a complete blood count with differential, serum creatinine concentration, and liver function studies. A chest radiograph should be part of the initial evaluation even if the chest examination is normal, as should routine urinalysis. Because routine radiographs are insensitive for detection of small nodular lesions, especially those caused by filamentous fungi, computed tomography (CT) should be performed to evaluate persistent fever, especially in the presence of airway or gastrointestinal symptoms.

Noninfectious causes of fever (e.g., drug fever) cannot be overlooked in neutropenic patients even though they might often require less urgent intervention. No biomarker has yet to be proved reliable in discriminating between severe infection and other causes of fever during neutropenia, although the utility of tests such as lipopolysaccharide-binding protein, interleukin-6 and interleukin-8, procalcitonin, presepsin, MCP-1 (monocyte chemoattractant protein-1), soluble TREM-1 (triggering receptor expressed on myeloid cells-1), C-reactive protein, and micro-RNAs is being studied. A heightened awareness of the possibility of a fungal infection is important.[3]

Multiple episodes of fever during prolonged hospitalization and neutropenia are not uncommon. Each episode requires comprehensive reassessment. After a documented infection, it should not be assumed that a subsequent episode of fever is caused by recrudescence of the same pathogen.

TABLE 260-4 APPROACH TO FEVER DURING CHEMOTHERAPY-INDUCED NEUTROPENIA

PAST AND CURRENT CLINICAL CONSIDERATIONS
What is the type and duration of immunologic deficiency?
Does the patient have any organ dysfunction that would predispose to particular infection?
Does the patient have any unique environmental or epidemiologic exposures?
What are the patient's prior infections and colonizing organisms?
What are the current and recently administered antimicrobial agents?
Are there any specific presenting signs or symptoms that suggest a particular type of infection or syndrome?

TREATMENT

Data support the liberal and prompt use of empirical antimicrobials in febrile neutropenic patients, selecting drugs that are active against the most likely pathogens based on the patients' epidemiologic exposures and colonizing organisms, especially in the gastrointestinal tract. An initial consideration in the management of fever during neutropenia is whether the patient requires hospitalization for therapy.[4] Risk assessment is an integral part of early evaluation to determine whether outpatient therapy is feasible. Risk assessment systems include the Multinational Association of Supportive Care in Cancer (MASCC) risk index score (Table 260-5), which is a validated predictor that can stratify patients for their risk of developing severe complications. However, current guidelines (Fig. 260-1) also consider other factors (such as the underlying disease, anticipated duration of neutropenia, other comorbid conditions that prompt patient access to a hospital, and the clinical judgment of the treating provider; Tables 260-6 and 260-7) when deciding whether outpatient management is appropriate for patients with febrile neutropenia.[5,6]

Progression of infection can occur rapidly in neutropenic hosts. The very high mortality rates associated with bacteremia, especially when caused by gram-negative bacteria, requires routine empirical therapies.[7] Antibiotics should be started as quickly as possible, preferably within an hour of recognition of fever during neutropenia, because delays in administering antibiotics may lead to prolonged hospital stays. The initial antibiotic choice should be tailored to patient and institutional variables (Table 260-2 and Fig. 260-2). In low-risk patients who can be potentially treated with oral antibiotics, starting combination therapy with a fluoroquinolone (e.g., ciprofloxacin, 750 mg twice daily) plus amoxicillin-clavulanate (875 mg/125 mg twice daily) is effective. In high-risk patients, admission is necessary for treatment and prompt administration of a broad-spectrum intravenous antibiotic regimen.

Monotherapy with a broad-spectrum β-lactam is generally associated with equal or better outcomes compared with the combination therapy,[A1,A2] but some evidence suggests that combination therapy may be preferred in patients who have septic shock. Current monotherapy options include third- and fourth-generation cephalosporins (e.g., cefepime 2 gm every 8 hours), antipseudomonal penicillins (e.g., piperacillin-tazobactam 4.5 gm every 6 hours), and carbapenems (e.g., meropenem 1 gm every 8 hours).[A3,A4]

The routine addition of vancomycin does not reduce all-cause or infection-related mortality and may be associated with increased adverse effects, including nephrotoxicity and rash. Nevertheless, empirical vancomycin use may be considered in specific clinical scenarios, such as documented or suspected catheter-related infection, gram-positive bacteremia pending final identification and susceptibility testing, colonization with methicillin-resistant *S. aureus*,

TABLE 260-5 THE MULTINATIONAL ASSOCIATION FOR SUPPORTIVE CARE IN CANCER (MASCC) INDEX

COMPONENTS OF THE MASCC INDEX

CLINICAL CHARACTERISTIC	SCORE*
Burden of illness (1 of the 3 options only):	
No or mild symptoms	5
Moderate symptoms	3
Severe symptoms	0
No hypotension (systolic BP >90 mm Hg)	5
No chronic obstructive pulmonary disease	4
Solid tumor or no prior fungal infection in patient with hematologic neoplasm	4
No dehydration (hydration with IV fluids not required)	3
Outpatient at onset of fever	3
Age <60 yr	2

*Maximum score: 26 (5 + 5 + 4 + 4 + 3 + 3 + 2). Low risk for complication = score ≥21; high risk for complication = score <21.

BP = blood pressure; IV = intravenous.

Data from Klastersky J, Paesmans M, Rubenstein EB, et al. The Multinational Association for Supportive Care in Cancer risk index: a multinational scoring system for identifying low-risk febrile neutropenic cancer patients. *J Clin Oncol*. 2000;18:3038-3051.

sepsis with hemodynamic instability pending culture results, pneumonia, and soft tissue infection. Use of vancomycin should be reassessed within 2 to 3 days when initiated for one of these conditions; if cultures fail to identify a resistant gram-positive pathogen, intravenous vancomycin should be discontinued.

Clinical response to the first few days of therapy is a critical determinant of the course of extended antimicrobial therapy. The median time to defervescence is shorter in low-risk than in high-risk patients (2 days vs. 5 to 7 days). If patients are stable yet still febrile during a period of prolonged and severe neutropenia, clinical judgment is required in deciding whether to maintain the initial regimen or to switch to an alternative regimen (Fig. 260-3).[8] Even if patients with neutropenia defervesce after 3 to 5 days of antibiotic therapy and cultures are negative, data are inconclusive as to the best subsequent strategy.[A5] The traditional strategy has been to continue empiric broad-spectrum antimicrobial therapy until recovery of the absolute neutrophil count, although this approach may not be possible in patients who are expected to have prolonged neutropenia. An alternative strategy is to discontinue empiric intravenous coverage or de-escalate to an oral antibiotic regimen. This latter strategy reduces total antibiotic exposure and has been shown to be safe for patients who are clinically stable and have been afebrile for at least 72 hours.[9] However, this strategy is associated with increased serious adverse outcomes in patients who are persistently febrile while receiving empiric broad-spectrum antibiotics.[A6,A7] If the neutrophil count recovers to above 500 cells/μL and fever persists, clinical judgment must be used to define the ongoing need for antimicrobial therapy while a search for the cause of the fever is continued. Clinical deterioration should trigger consideration of infections resistant to the empirical regimen.

Causes of persistent fever can be either infectious or noninfectious. Noninfectious causes include drug reactions (Chapter 234), transfusion reactions (Chapter 162), pulmonary emboli (Chapter 68), splenic infarcts, and underlying malignant disease. Persistent fever (Fig. 260-4) may indicate infection by a microorganism that is resistant or not covered by the empirical antibiotics chosen, or a loculated site of infection such as an abscess that also requires drainage for cure. In addition, nonbacterial pathogens should be considered, such as fungi (especially *Candida* and *Aspergillus* species) and should prompt evaluation and consideration of antifungal empirical therapies in the setting of fever that persists more than 4 to 7 days. Data are inconclusive as to whether early antifungal therapy guided by the depth and duration of the neutropenia is as good as routine empiric antifungal treatment.[A8,A9] Many drugs have been evaluated and shown to be effective in this setting, including azole drugs, echinocandins, and polyenes (Chapter 307).

Persistently compromised hosts may remain febrile for weeks without identification of the cause. For a patient who has persistent fever and in whom no pathogen is identified, the duration of therapy should be based on an integration of clinical data and the best estimate of the direction of the host's course. Therapy can be discontinued in stable, afebrile patients, assuming that the absolute neutrophil count exceeds 500 cells/μL. If broad-spectrum antibacterial therapy is discontinued, the patient should be monitored carefully. For patients whose neutrophil counts remain below 500 cells/μL, particularly the subset with severe profound neutropenia of less than 100 cells/μL, it is prudent to continue empirical antibacterial and antifungal therapy, with reappraisal of all diagnostic measures.

Granulocyte colony-stimulating factors can sometimes be useful for the prevention of febrile neutropenia.[A10] (see Chapter 153). For established fever in neutropenic patients, evidence-based guidelines[10] support the use of colony-stimulating factors in patients who are at high risk for infection-associated complications and poor clinical outcomes, such as patients with anticipated long and profound durations of neutropenia, advanced age, uncontrolled primary disease, hemodynamic compromise, pneumonia, and invasive fungal infections.

FEBRILE NEUTROPENIA SYNDROME

Fever in immunocompromised hosts can manifest as a variety of clinical syndromes other than just fever (Table 260-8). Common infectious and noninfectious syndromes can involve the skin, lungs, gastrointestinal tract, and CNS.

CUTANEOUS SYNDROMES

In immunocompromised patients with fever, a skin examination often can provide clues to the diagnosis.

Infectious Causes

Cutaneous manifestations can provide a clue to bacteremia, and aspiration and culture of suspicious lesions can be as valuable as a blood culture. Ascending streptococcal or staphylococcal cellulitis (Chapter 408) can occur in both immunocompromised and immunocompetent patients. Metastatic abscesses are a well-recognized complication of the *S. aureus* bacteremia syndrome. Necrotizing vasculitis is classically associated with *P. aeruginosa* infections (Chapter 282); its cutaneous lesion of ecthyma gangrenosum is an erythematous, indurated target or "bull's-eye" lesion with an area of central necrosis that can appear in crops (Fig. 260-5 and Chapter 408). However, other gram-negative endotoxin-producing bacteria have been associated with similar cutaneous lesions.

Cutaneous mycobacterial infections can occur in patients with chronic T-cell deficiency and impaired cell-mediated immunity following stem cell or solid organ transplantation or as a consequence of treatment with TNF antagonists. Nontuberculous mycobacteria (Chapter 300) typically cause tender, erythematous nodular lesions that may ulcerate. These lesions can arise either following direct inoculation (e.g., following trauma or cosmetic surgery) or, typically in immunocompromised patients, as a consequence of disseminated disease and hematogenous seeding (Chapter 300). Important species include rapidly growing nontuberculous mycobacteria (i.e., *Mycobacterium chelonae, Mycobacterium abscessus*, and *Mycobacterium fortuitum*), *Mycobacterium haemophilum* often with concurrent pulmonary disease, and *Mycobacterium marinum* following fresh or salt water exposures (Fig. 260-6). *M. tuberculosis* (Chapter 299) is a rare cause of skin disease but should be considered with suggestive epidemiology; it can arise due to contiguous spread, for example, from an infected lymph node (e.g., scrofuloderma) or with disseminated infection (e.g., lupus vulgaris).

Nocardia species are another important cause of skin and subcutaneous infections in immunocompromised and noncompromised hosts (Chapter 306). *Nocardia*, which are environmentally ubiquitous saprophytes found in the soil, can cause local infection following direct inoculation; however, cutaneous nocardiosis may also be the first sign of systemic disease in immunocompromised hosts. Identification of *Nocardia* skin or soft tissue infection in immunocompromised patients, particularly in those with no history of penetrating trauma, should prompt evaluation of disseminated infection, including imaging of the lungs and brain. Cutaneous nocardiosis can be variable in presentation, including subcutaneous nodules (often with a sporotrichoid-like lymphocutaneous distribution), ulcers, abscesses, pyoderma, and cellulitis.

In the neutropenic host, disseminated fungal infections may be initially recognized by characteristic cutaneous lesions. Disseminated candidiasis in such individuals can present with diffuse maculopapular, erythematous, and sometimes tender lesions. The appearance of cutaneous lesions typically changes in character with engraftment of neutrophils (Fig. 260-7). Disseminated infections caused by filamentous organisms such as *Aspergillus* species (Chapter 311) cause similar lesions, but usually fewer in number and more often with some component of central necrosis. Other filamentous fungi, namely those with which infection is characterized by a high fungal burden, such as *Fusarium* species, typically cause more skin lesions in multiple stages of evolution, ranging from papules to larger erythematous lesions with central necrosis. Multiple filamentous fungi such as *Aspergillus* species and Zygomycetes can also cause primary cutaneous lesions, especially with a breach in skin integrity. Infection with *Cryptococcus neoformans* (Chapter 309) can be accompanied

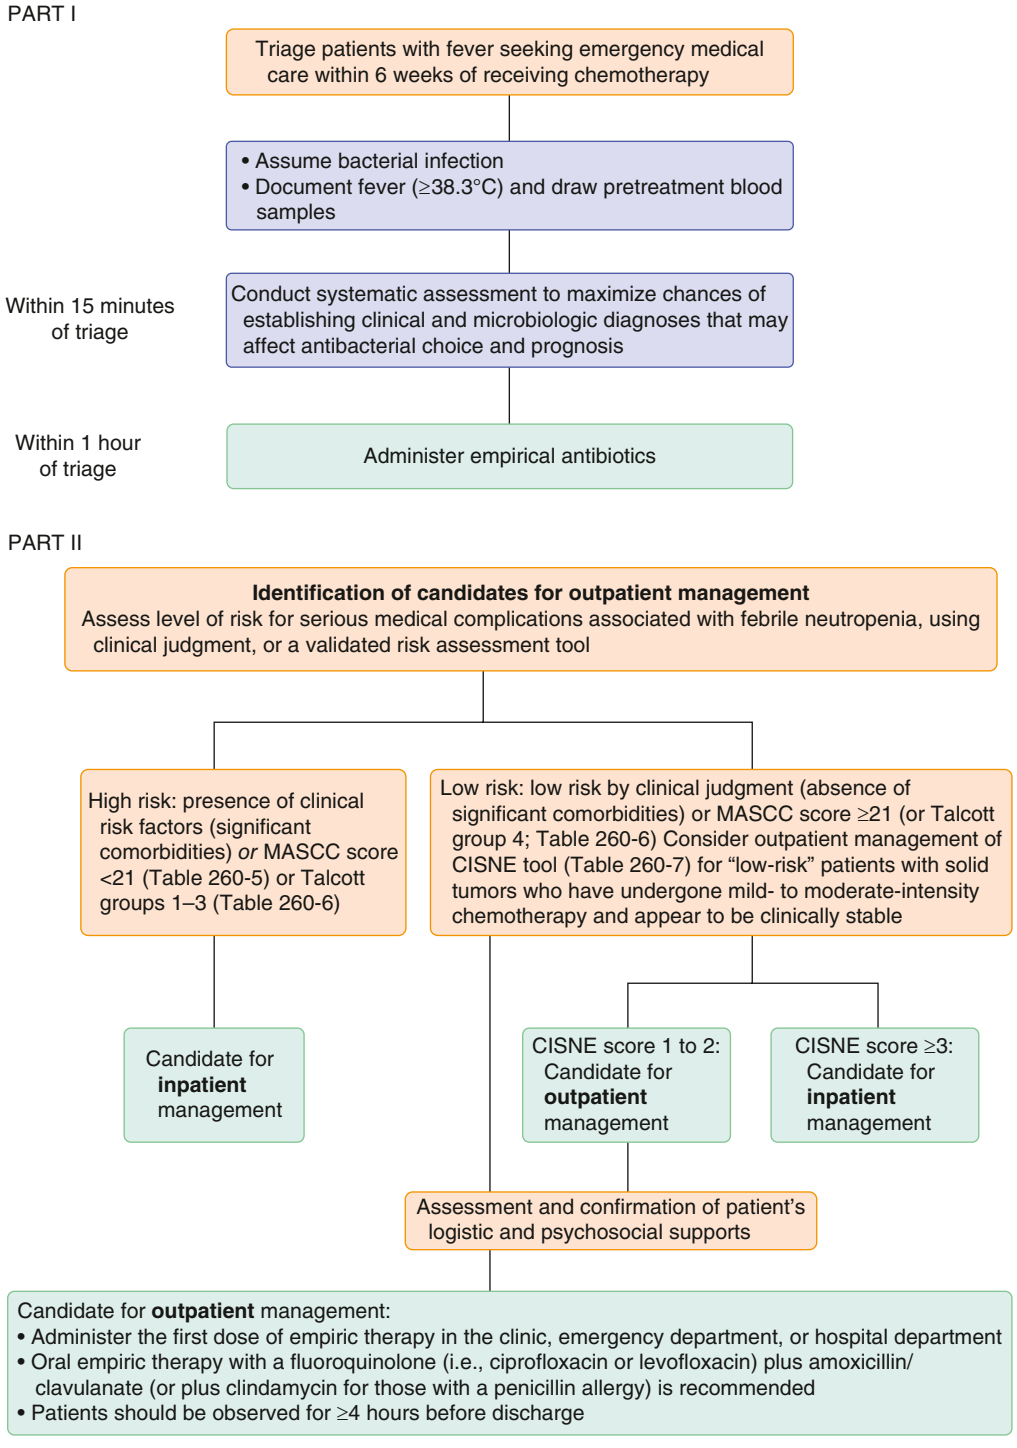

FIGURE 260-1. Summary of recommendations for outpatient management of fever and neutropenia in adults treated for malignancy. Outpatient management of fever and neutropenia in adults treated for malignancy: American Society of Clinical Oncology and Infectious Diseases Society of America clinical practice guideline update. *J Clin Oncol*. 2018;36:1443-1453.)

TABLE 260-6 TALCOTT GROUP CLASSIFICATION

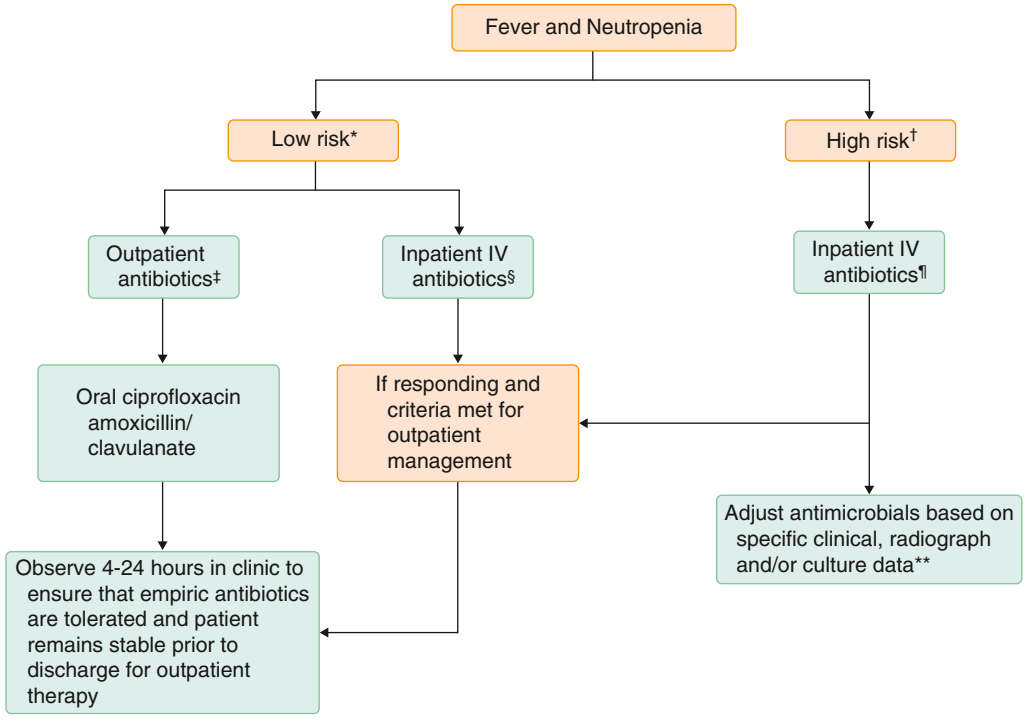
GROUP	CHARACTERISTIC
I	Inpatients (at the time of fever onset)
II	Outpatients with acute comorbidity requiring, by itself, hospitalization
III	Outpatients without comorbidity but with uncontrolled cancer
IV	Outpatients with cancer controlled and without comorbidity

Adapted from Taplitz RA, Kennedy EB, Bow EJ, et al. Outpatient management of fever and neutropenia in adults treated for malignancy: American Society of Clinical Oncology and Infectious Diseases Society of America clinical practice guideline update. *J Clin Oncol*. 2018:36:1443-1453.

TABLE 260-7 THE CLINICAL INDEX OF STABLE FEBRILE NEUTROPENIA (CISNE)

EXPLANATORY VARIABLE	NO. OF POINTS
Eastern Cooperative Oncology Group performance status ≥ 2	2
Chronic obstructive pulmonary disease	1
Chronic cardiovascular disease	1
National Cancer Institute Common Toxicity Criteria mucositis of grade ≥ 2	1
Monocytes < 200/μL	1
Stress-induced hyperglycemia	2

The six variables are integrated into a score ranging from 0 to 8, which classifies patients into three prognostic classes: low risk (0 points), intermediate risk (1 to 2 points), and high risk (≥3 points).
Adapted from Taplitz RA, Kennedy EB, Bow EJ, et al. Outpatient management of fever and neutropenia in adults treated for malignancy: American Society of Clinical Oncology and Infectious Diseases Society of America clinical practice guideline update. *J Clin Oncol*. 2018:36:1443-1453.



* Low Risk = anticipated neutropenia ≤7 days and clinically stable and no medical comorbidities.
† High Risk = anticipated neutropenia >7 days, *or* clinically unstable, *or* any medical comorbidities.
‡ If able to tolerate and absorb; caregiver, access, and transportation are available; patient and physician decide.
§ If there is documented infection requiring IV antibiotics; there is gastrointestinal intolerance; patient and physician decide.
¶ Empiric antibiotic monotherapy with any of the following: piperacillin/tazobactam, or carbapenem, or ceftazidime, or cefepime.
** For example: vancomycin and linezolid for cellulitis or pneumonia; add aminoglycoside and switch to carbapenem for pneumonia or gram-negative bacteremia; metronidazole for abdominal symptoms of suspected *C. difficile* infection.

FIGURE 260-2. Initial management of fever (≥38.3°C) and neutropenia (<500 cells/μL). Limited data to support recommendation. IV = intravenous. (Modified from Freifeld AG, Bow EJ, Sepkowitz KA, et al. Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2011;52:e56-e93.)

by cutaneous involvement, with manifestations ranging from molluscum-like lesions to primary cutaneous cellulitis, which may be especially common in solid organ transplant recipients. Cutaneous lesions are an opportunity to establish diagnosis through aspiration, biopsy, and culture.

Morbilliform eruptions or maculopapular exanthems are frequent in neutropenic and transplant recipients. These rashes can be caused by drug reactions, GVHD, and numerous viral infections. Primary infection and reactivation with herpesviruses such as cytomegalovirus (Chapter 347) and Epstein-Barr virus (Chapter 348) can be accompanied by rashes. Human herpesvirus 6, the primary cause of roseola infantum in childhood, leads to latency and can cause disease in immunocompromised hosts both by reactivation and by primary infection. Disease can be accompanied by fever, rash, myelosuppression, and involvement of other organ systems (e.g., CNS). In immunocompromised patients, adenovirus (Chapter 333) can be both primarily acquired, usually through the respiratory tract, and reactivated; it causes fever, rash, and potentially disease involving multiple organ systems (lungs, gastrointestinal tract, kidneys, liver, CNS). In stem cell transplant recipients, the constellation of fever, rash, diarrhea, and hepatitis may be confused for severe GVHD. Parvovirus B19 infection (Chapter 342) can be severe in immunocompromised hosts and associated with fever, rash, and manifestations of hemophagocytosis, although there are other infectious causes of hemophagocytic syndromes as well (Chapter 155). The characteristic vesicular rash of varicella reactivation (Chapter 346) is relatively frequent in stem cell and solid organ transplant recipients with chronic T-cell deficiencies, especially in the absence of antiviral prophylaxis. Disseminated disease in immunocompromised patients is associated with high mortality rates unless prompt antiviral therapy (Chapter 328) is initiated. Antivirals administered as prophylaxis in high-risk recipients of stem cell and solid organ transplants can decrease both early morbidity and late mortality associated with herpes simplex virus, varicella-zoster virus, and cytomegalovirus disease, although drug-related toxicities must be considered in risk-benefit calculations.

Noninfectious Causes

Numerous noninfectious causes of rashes and lesions are common in immunocompromised individuals, particularly drug-induced hypersensitivity syndromes (Chapter 234) that can be both mild and severe and rarely progress to life-threatening toxic epidermal necrolysis (Fig. 403-7).

Sweet syndrome (Chapter 406), or acute febrile neutrophilic dermatosis, is characterized by skin lesions with neutrophilic infiltration in the dermis (see Fig. 406-29). It may appear during impending neutrophil recovery, treatment with granulocyte colony-stimulating factor, in association with numerous drugs, or as a paraneoplastic manifestation, particularly in hematologic malignancies (most commonly acute myelogenous leukemia). Biopsy with appropriate microbial stains and culture is essential to distinguish these lesions from infectious causes of ecthyma gangrenosum and other disseminated infections, such as those caused by mycobacteria, *Nocardia*, and fungi.

RESPIRATORY SYNDROMES

In febrile immunocompromised patients, respiratory complications can progress rapidly to respiratory failure (Chapter 90), so prompt diagnosis is critical (see Table 260-8).

Infectious Causes

Pneumonia should be suspected in a patient who has respiratory symptoms as manifested by cough, shortness of breath, chest pain, and hypoxia, even in the absence of radiographic abnormalities initially. Although opportunistic infections are always a consideration, pneumonia in immunocompromised patients is more often caused by community-acquired pathogens (Chapter 85) such as pneumococci (Chapter 268) and *Haemophilus influenzae* (Chapter 277) that can cause lobar or diffuse pneumonia.[11] Patients on ventilators are at risk for secondary gram-negative bacillary pneumonia or staphylococcal pneumonia.

Opportunistic fungi have been increasingly recognized as causes of lung infection in immunocompromised neutropenic patients and transplant recipients.

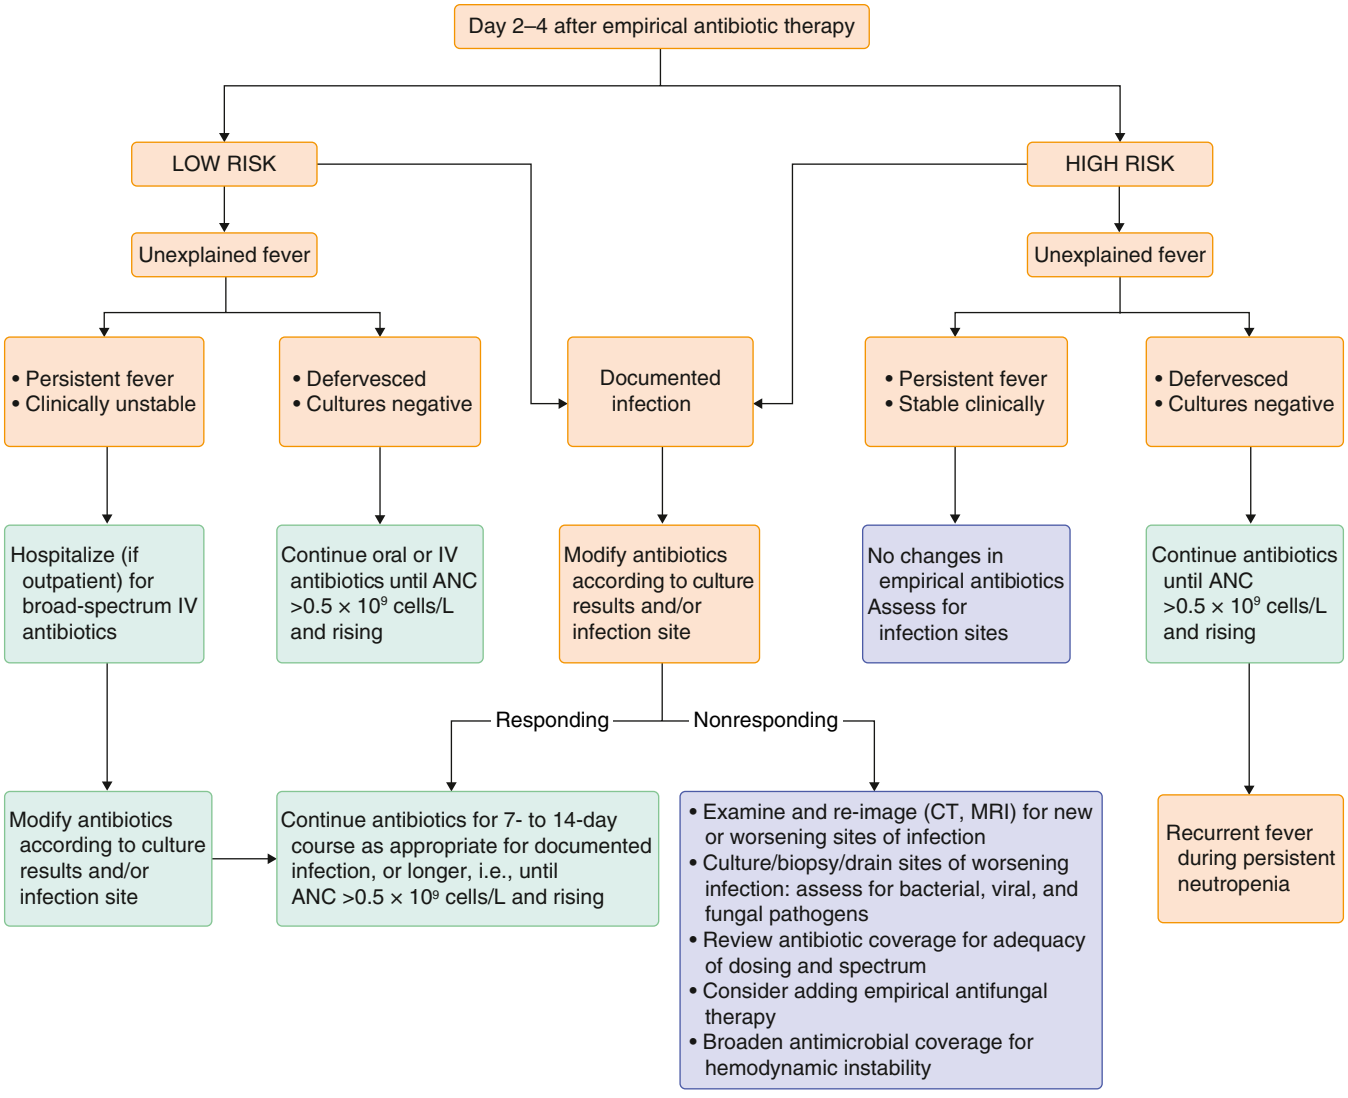


FIGURE 260-3. Reassessment after 2 to 4 days of empirical antibiotic therapy. ANC = absolute neutrophil count; CT = computed tomography; IV = intravenous; MRI = magnetic resonance imaging. (Modified from Freifeld AG, Bow EJ, Sepkowitz KA, et al. Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2011;52:e56-e93.)

Endemic mycoses (Chapter 308) such as blastomycosis, coccidioidomycosis, and histoplasmosis may be manifested as acute pneumonia after recent exposure in immunocompromised patients, making a travel history mandatory. Although *Candida* species (Chapter 310) commonly colonize indwelling vascular and urinary catheters, candidal pneumonia is unusual in the absence of systemic candidiasis. Although classically associated with an "interstitial pattern" of lung infiltration, *Pneumocystis* species (Chapter 313) pneumonia can be manifested as local consolidation or pulmonary nodules, exhibiting granulomatous inflammation on pathologic examination. Filamentous fungi, including *Aspergillus* (Chapter 311), Zygomycetes, *Fusarium* species, and *Scedosporium* species, are challenging to treat. From an initial focus, *Aspergillus* infection can spread through the pulmonary vasculature, which sets the stage for localized hemorrhage, creating a halo sign on CT scan, and infarction and necrosis.[12] Pulmonary infection can progress to cavitary lesions. Invasive pulmonary aspergillosis is usually caused by *Aspergillus fumigatus*. These organisms can also cause primary airway disease, with features typical of tracheobronchitis, with or without findings on CT scan, this infection is particularly well described in lung transplant recipients, who may also have involvement of the bronchial anastomosis.

Patients who are treated with biologic immune response modifiers (Chapter 29) (especially TNF antagonists in the setting of autoimmune or other inflammatory diseases such as rheumatoid arthritis, psoriasis, and inflammatory bowel diseases) are at high risk for severe pulmonary infection caused by reactivation of *M. tuberculosis* (Chapter 299). The same patients are also at increased risk for invasive fungal infections, including reactivation of endemic infections (Chapter 308) such as histoplasmosis, thereby warranting enhanced screening and a high level of suspicion for disease.

A particularly common concern is reactivation pneumonitis caused by members of the herpesvirus family, especially cytomegalovirus (Chapter 347), which occurs most frequently in the setting of chronic T-cell depression associated with transplantation. Common respiratory viruses such as influenza virus (Chapter 332) and respiratory syncytial virus (Chapter 330) infect immunocompromised hosts with the same frequency as the general population but are more likely to cause lower respiratory tract disease with the potential for progression to respiratory failure and death. Hosts with suppressed cellular immunity due to organ transplantation or anticancer treatment also experience increased adverse outcomes from coronavirus 2019 disease (COVID-19; Chapter 336), although the relative contribution of immunosuppression versus underlying comorbidities remains to be determined.[13] Patients who have defects in cellular immunity typically exhibit higher viral loads and prolonged shedding, thereby causing concern for the emergence of antiviral resistance and infection control.

Noninfectious Causes

Noninfectious causes of pulmonary infiltrates in immunosuppressed hosts include early complications of chemotherapy administration (e.g., diffuse alveolar damage and hemorrhage) and late complications of GVHD and organ rejection (e.g., bronchiolitis obliterans syndromes). Certain drugs that are frequently administered in these populations of patients, like sirolimus, can cause direct lung toxicity.

GASTROINTESTINAL SYNDROMES

In febrile immunocompromised patients, diarrhea can be disabling and life-threatening. Prompt evaluation is key to determine the cause (see Table 260-8).

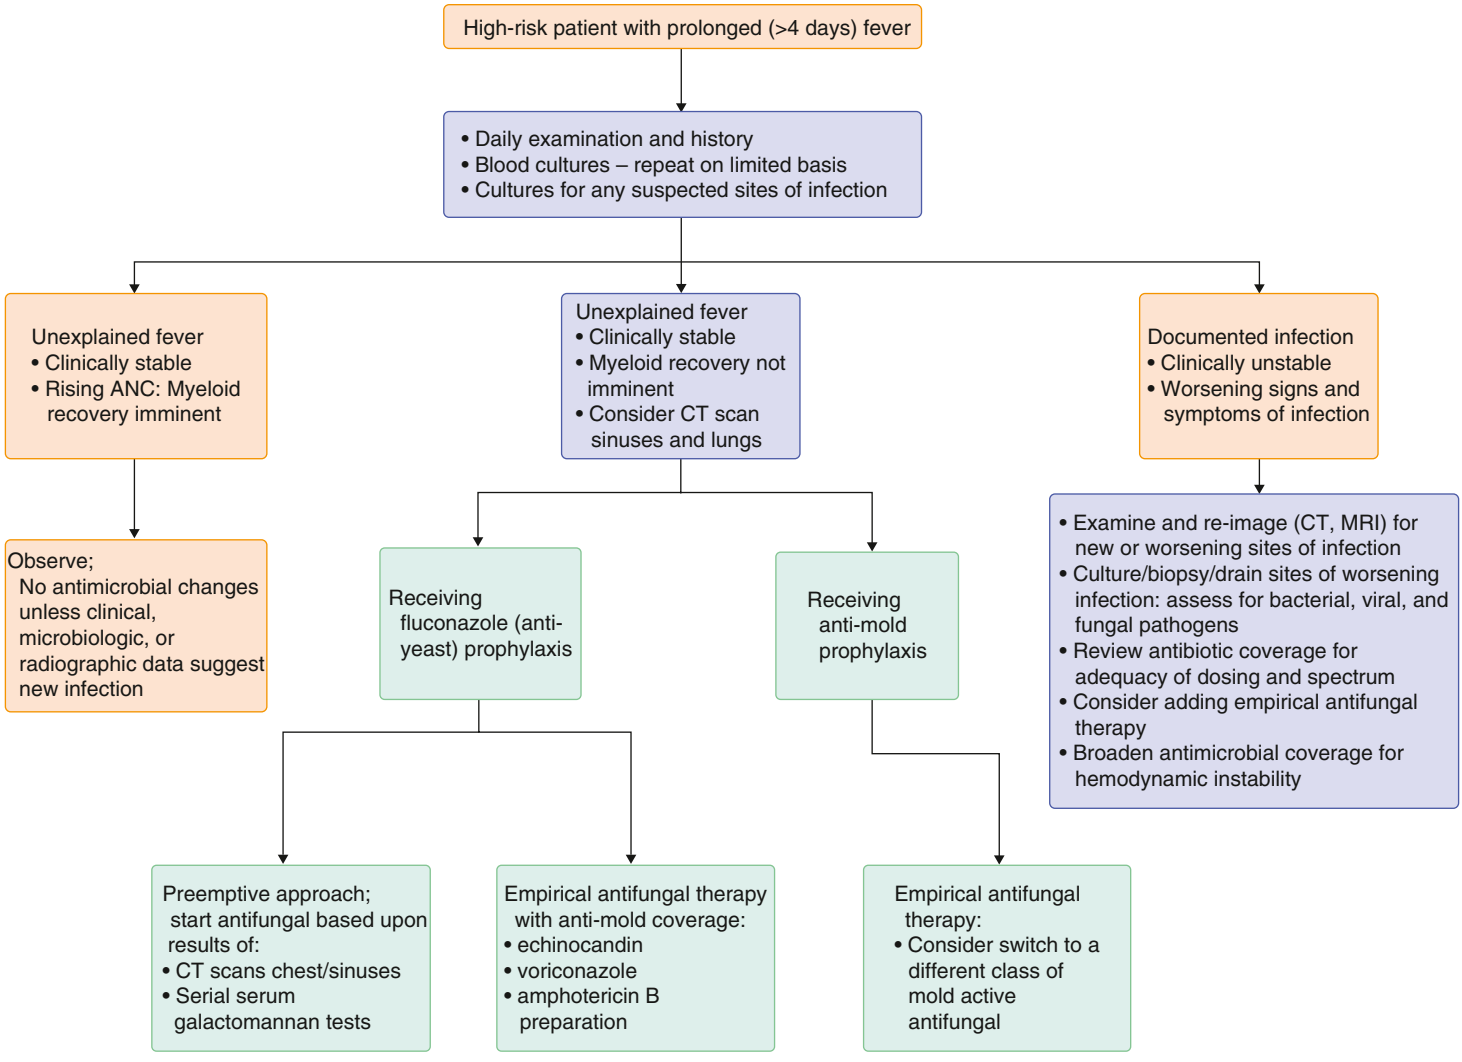

FIGURE 260-4. High-risk patient with fever after 4 days of empirical antibiotics. ANC = absolute neutrophil count; CT = computed tomography; MRI = magnetic resonance imaging. (Modified from Freifeld AG, Bow EJ, Sepkowitz KA, et al. Clinical practice guideline for the use of antimicrobial agents in neutropenic patients with cancer: 2010 update by the Infectious Diseases Society of America. *Clin Infect Dis*. 2011;52:e56-e93.)

Diarrhea in an immunocompromised host can be caused by a wide variety of infectious and noninfectious etiologies (Chapter 126),[14] including conventional enteric pathogens such as *Salmonella* (Chapter 284), *Shigella* (Chapter 285), and *Campylobacter* (Chapter 279). Currently and recently hospitalized patients who have received courses of antibiotic treatment are commonly infected with *Clostridioides difficile* (Chapter 271). *C. difficile* colitis can be both severe and persistent in immunosuppressed hosts. More recently, norovirus (Chapter 350) has emerged as an important cause of chronic gastroenteritis in immunocompromised patients, in whom diagnoses have been commonly elusive and misapplied to noninfectious syndromes (e.g., GVHD), and outcomes can be poor. Several intestinal protozoa are associated with diarrhea in compromised patients. Three acid-fast–staining protozoa (*Cryptosporidium* species, *Cystoisospora belli*, and *Cyclospora cayetanensis*) are associated with predisposing impairments in cell-mediated immunity (see Chapters 321 and 324). *Giardia lamblia* (Chapter 322) is classically associated with hypogammaglobulinemia. The Microsporidia (Chapter 324) are a family of eukaryotic obligate intracellular parasites once thought to be protozoa but more recently placed taxonomically closer to fungi. In addition to causing diarrhea in immune-suppressed patients, they are distinguished by the ability to cause extraintestinal disease in virtually any other organ.

Because acute and chronic diarrhea in immunocompromised patients can be caused by a wide array of bacterial, viral, and protozoal pathogens with broadly overlapping clinical presentations, multiplex molecular diagnostic panels are key important diagnostic tools.[15] Caution should be exercised in interpretation, however, because a positive result may reflect active infection or asymptomatic colonization. The small intestine is the primary site where calcineurin inhibitors (e.g., cyclosporine, tacrolimus) are absorbed and metabolized; toxic blood concentrations of calcineurin inhibitors may be a sign of enteritis, for example, due to rotavirus (Chapter 350) or *Cryptosporidium* (Chapter 321), perhaps as a consequence of altered drug metabolism.

Cytomegalovirus (Chapter 347) is a major cause of gastrointestinal disease in transplant recipients and increasingly recognized in patients with impaired cell-mediated immunity not due to transplantation or AIDS. Cytomegalovirus can involve the entire digestive tract from esophagus to anus, and patients typically present with signs and symptoms of disseminated disease, including fever, malaise, and bone marrow suppression (i.e., a mononucleosis-like syndrome). Symptoms of cytomegalovirus gastritis, enteritis, and colitis include anorexia, nausea, abdominal discomfort, and diarrhea. Cytomegalovirus infection also causes mild elevations in hepatic enzymes and, rarely, fulminant hepatitis or pancreatitis, typically in the context of primary infection after liver transplantation or pancreas transplantation, respectively. Quantitative cytomegalovirus nucleic acid amplification assays can establish a diagnosis of cytomegalovirus gastrointestinal disease, but testing of plasma or whole blood can occasionally be negative because tissue-invasive disease is isolated to the alimentary tract. In these cases, endoscopy is required to establish a diagnosis. Indeed, because colitis and diarrhea in immunocompromised patients can be caused by such a wide range of problems, including multiple infections, focal Epstein-Barr virus–associated post-transplantation lymphoproliferative disorder (Chapter 348), GVHD (Chapter 163), and drug-induced toxicity, uncertainty in diagnosis or failure of response to appropriate treatment requires further evaluation with endoscopy.

Individuals who have received long courses of chemotherapy, radiation, and antibiotics commonly experience *Candida* (Chapter 310) mucosal overgrowth in the mouth and esophagus. Herpes simplex virus (Chapter 345) and cytomegalovirus (Chapter 347) can cause symptoms identical to those of *Candida* esophagitis (Chapter 124). In severely neutropenic patients, anaerobic

CMV = cytomegalovirus; EBV-PTLD = Epstein-Barr virus–post-transplantation lymphoproliferative disorder; GVHD = graft-versus-host disease; HHV-6 = human herpes virus 6; HSV = herpes simplex virus; MMF = mycophenolate mofetil; PRES = posterior reversible encephalopathy syndrome; RSV = respiratory syncytial virus; SARS-CoV-2 = severe acute respiratory syndrome coronavirus 2; VZV = varicella-zoster virus

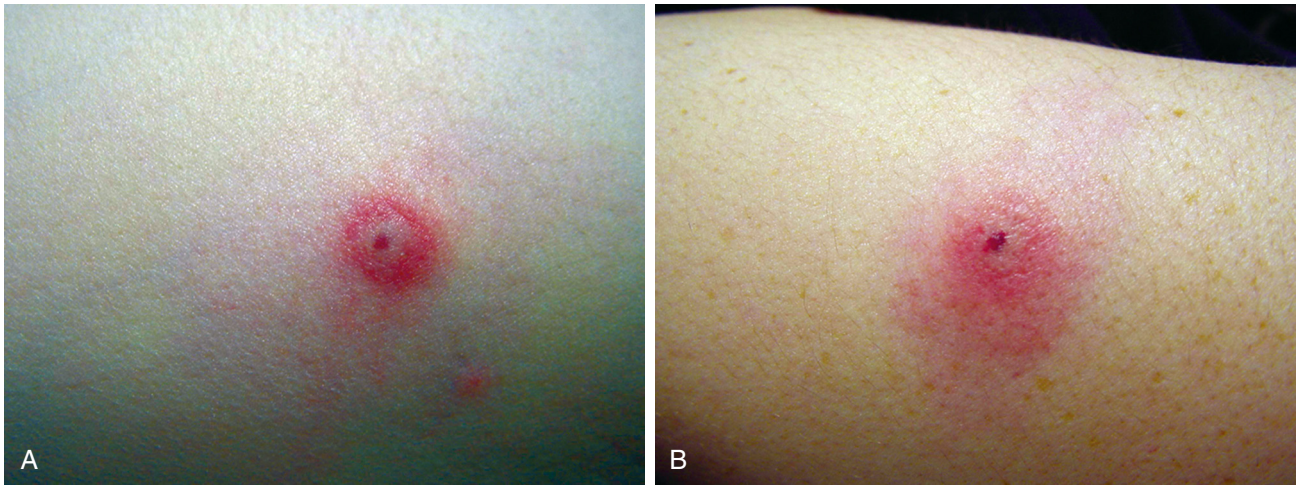

FIGURE 260-5. Ecthyma gangrenosum. A 28-year-old woman with fever and neutropenia while receiving chemotherapy for acute leukemia developed several tender edematous papules on her thighs. **A,** Central crust and surrounding erythema are shown. **B,** The papules became necrotic during 1 to 2 days, with the formation of black, well-demarcated eschar. Cultures from blood and the necrotic eschar grew *Pseudomonas aeruginosa*. (© DermAtlas; http://www.DermAtlas.org.)

streptococci and gram-negative pathogens such as *P. aeruginosa* (Chapter 282) can cause severe mucositis and pharyngitis. In cancer patients, these organisms take advantage of the cytotoxic effects of chemotherapy, which promotes sloughing of mucosal surfaces and subsequently predisposes to infection.

Neutropenic patients may also develop enterocolitis that can be of mixed anaerobic and aerobic bacterial origin. Neutropenic enterocolitis,[16] also known as typhlitis or ileocecal syndrome, results from chemotherapeutic damage to the intestinal mucosa in the setting of neutropenia. Presentation usually includes fever, abdominal pain, nausea, vomiting, and diarrhea. Because neutropenic enterocolitis can rapidly progress to intestinal perforation, sepsis, and multisystem organ failure, prompt diagnosis and aggressive medical or surgical intervention are required.

FIGURE 260-6. ***Mycobacterium marinum*. A 20-year-old man with Crohn disease receiving infliximab developed progressively worsening nonhealing foot ulcers following trauma and exposure to brackish water 2 years earlier. Biopsy cultures of the ulcer grew *Mycobacterium marinum*. A, Two necrotic ulcers with central eschars, surrounding erythema, and pedal edema at the time of diagnosis. B, After 1 month of treatment, granulation tissue is evident in the base of the ulcer, and erythema and edema are reduced. C, After 10 months of treatment, the ulcers have closed with residual scars and hyperpigmentation.**

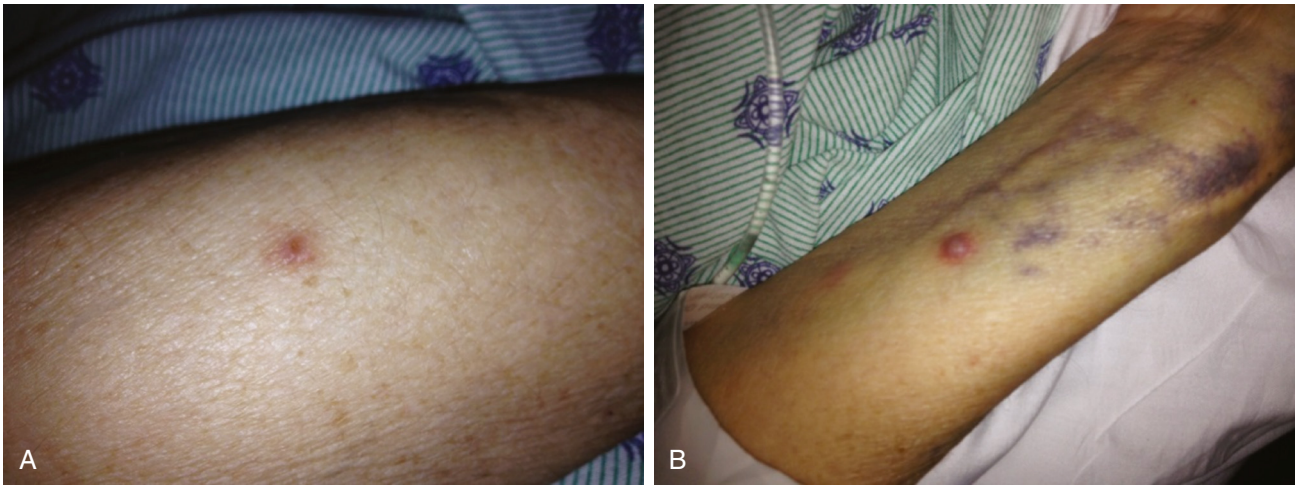

FIGURE 260-7. Disseminated candidiasis. A 60-year-old woman with fever during neutropenia that developed after receipt of therapy for acute leukemia developed tender papular lesions on her extremities, trunk, and back. A, Blood cultures returned positive for *Candida tropicalis*. B, After resolution of neutropenia, lesions developed a more pustular appearance.

NEUROLOGIC SYNDROMES

In febrile immunocompromised patients, neurologic signs or symptoms are often life-threatening, so rapid diagnosis is mandatory (see Table 260-8).

Infectious Causes

Brain abscess (Chapter 382) or meningitis (Chapter 381) can be caused in immunocompromised patients by gram-positive or gram-negative bacteria as well as by anaerobes. *Listeria monocytogenes* (Chapter 272) is a particularly common cause of meningitis in these patients. Encapsulated bacteria such as pneumococci and staphylococci can cause metastatic CNS disease and meningitis. In patients with impaired cell-mediated immunity, *C. neoformans* (Chapter 309) is a leading cause of CNS infection, usually presenting as cryptococcal meningitis or meningoencephalitis and sometimes as parenchymal mass lesions of the brain. *Aspergillus* species (Chapter 311) can infect the CNS both by direct sinus invasion and by hematogenous spread. Patients with impaired cellular immunity can develop CNS infection with *Toxoplasma gondii* (Chapter 320), *M. tuberculosis* (Chapter 299), *H. capsulatum* (Chapter 308), or *Nocardia* species (Chapter 306), either through severe infection by latent organisms or by reactivation. CNS syphilis (Chapter 295) should also be considered in patients with severe immunologic impairment.

Among the many viral etiologies of meningoencephalitis (Chapter 383) in immunocompromised individuals are enteroviruses (Chapter 349), measles, herpes simplex virus (Chapter 345), cytomegalovirus (Chapter 347), varicella zoster virus (Chapter 346), and human herpesvirus 6. Progressive multifocal leukoencephalopathy caused by JC polyomavirus (Chapter 341) may occur in those with chronic CD4 lymphocytopenia and in recipients of hematopoietic stem cell or solid organ transplants as well as individuals treated with natalizumab, rituximab, and possibly other immunomodulatory monoclonal antibodies. Transplant recipients are also at increased risk for meningoencephalitis caused by West Nile virus (Chapter 352). Patients with CNS symptoms presenting early after transplantation might be suspected of having severe infections acquired from the donor, including West Nile virus, rabies (Chapter 383), HIV, lymphocytic choriomeningitis virus (Chapter 381), Zika virus (Chapter 352), or other viruses known to be transmitted through organ donation.

Noninfectious Causes

In addition to opportunistic infection, noninfectious causes of neurologic symptoms must be considered in immunocompromised patients, including drug toxicity, immunologic disorders, paraneoplastic syndromes, and Guillain-Barré syndrome. Posterior reversible encephalopathy syndrome should be in the differential diagnosis of neurologic complications in transplant recipients, patients with autoimmune diseases, and patients who are receiving high doses of cancer chemotherapy, particularly when the clinical presentation includes the sudden onset of severe "thunderclap" headache, seizures, confusion, and visual disturbance. This syndrome can be caused by endothelial injury, vasospasm, or edema associated with certain drugs such as calcineurin inhibitors (e.g., cyclosporine, tacrolimus). The diagnosis can be confirmed by characteristic CT or magnetic resonance imaging patterns of predominantly posterior cerebral edema and angiographic evidence of reversible vasoconstriction.

261 PREVENTION AND CONTROL OF HEALTH CARE–ASSOCIATED INFECTIONS

DAVID P. CALFEE

THE BURDEN OF HEALTH CARE–ASSOCIATED INFECTIONS

EPIDEMIOLOGY

The Centers for Disease Control and Prevention (CDC) defines health care–associated infections as infections that patients acquire during the course of receiving health care treatment for other conditions. *Nosocomial infection* is a term that refers specifically to a health care–associated infection that develops in association with hospital care. The development of infection during the course of health care is not, however, limited to the acute care hospital setting. Thus, *health care–associated infection*, which is the preferred term, refers to the broader spectrum of infections that develop during the course of health care, wherever that care may be provided, including acute care hospitals, long-term care facilities, rehabilitation facilities, dialysis facilities, infusion centers, outpatient practices, and even the patient's home during the receipt of home care services.

The most extensive data regarding the incidence of and outcomes associated with health care–associated infections come from acute care hospital settings. Each year, an estimated 700,000 or so health care-associated infections occur in U.S. hospitals (Table 261-1), a huge number but a significant reduction from 4% to 3.2% of admitted patients since 2011.[1] Approximately 1 of every 30 patients admitted to U.S. hospitals develops a health care–associated infection, thereby making health care–associated infection one of the most common complications associated with the receipt of health care. Moreover, these data indicate that health care–associated infections are one of the top 10 causes of death in the United States. Whereas many of these health care–associated infection-associated deaths occur among patients who are already severely ill and who have a high likelihood of death due to their underlying disease, a substantial proportion of health care–associated infection-related deaths occur among persons who were otherwise expected to survive their hospitalization. In one study, about 30% of unexpected in-hospital deaths were determined to be possibly or probably related to health care–associated infections. In addition to an increased risk of death, patients who develop health care–associated infections suffer a number of other adverse outcomes, including prolonged hospital stays, additional medical interventions and antibiotic treatment, discomfort, and loss of function and income. These statistics are particularly concerning when they are considered with the knowledge that many of these infections are preventable. In fact, a systematic review found that 55 to 70% of four of the most common types of health care–associated infections are preventable through the use of currently available, evidence-based preventive strategies (see Table 261-1).

Although the majority of health care–associated infection statistics come from acute care hospitals, data demonstrate that health care–associated infections are significant problems in other health care settings as well. Point prevalence surveys conducted in European and the U.S. Veterans Affairs system long-term care facilities found that the prevalence of health care–associated infection among long-term care facility residents ranged from 2.4 to 5.2%. The overall burden of health care–associated infection among long-term care facility residents has been estimated to be 1.64 to 3.83 million infections per year in the United States and at least 2.6 million infections per year in Europe. Vascular access–related infections are the most common health care–associated infections among patients requiring chronic hemodialysis for end-stage renal disease, with a reported incidence ranging from 0.16 per 100 patient-months for patients with arteriovenous fistulas to 1.83 episodes per 100 patient months for patients with central venous catheters, and they are associated with increased morbidity, hospitalization, and death. The magnitude of health care–associated infections related to care provided in other settings, such as ambulatory surgery and endoscopy centers, has not been as thoroughly studied, but such infections have been well described.

PATHOBIOLOGY

Health care–associated infections can be caused by organisms that are a part of the patient's normal microbiota (i.e., endogenous infection) or by pathogens

ABSTRACT

Health care–associated infections are a substantial cause of morbidity and mortality among persons receiving health care. These infections may be caused by organisms that are part of a patient's normal microbiota ("endogenous" organisms) or by organisms acquired during the course of health care ("exogenous" organisms). Antimicrobial resistance among many of the common bacterial causes of health care–associated infections (e.g., *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Acinetobacter* species) has become a major treatment challenge and has been associated with higher rates of death and other adverse outcomes. Factors that increase the risk of health care–associated infection include disruption of normal host defenses as a result of invasive medical devices, surgical procedures, and immunosuppressive medications; alteration of the patient's normal microbiota, as can occur with receipt of antibiotics; and exposure to exogenous pathogens during the receipt of health care. Many underlying medical conditions can also predispose patients to the development of health care–associated infections. Although the epidemiology of health care–associated infections is complex, many of these infections are the result of a failure to implement basic infection prevention practices. Thus, a large proportion of health care–associated infections could be prevented by improving adherence to currently recommended, evidence-based, infection prevention strategies. These prevention strategies include, but are not limited to, hand hygiene, use of aseptic or sterile technique during invasive procedures, safe injection practices, proper cleaning and disinfection of medical equipment and high-touch surfaces within health care facilities, prompt removal of medical devices that are no longer medically indicated, and judicious use of antibiotics.

prevention
device-related infection

acquired during exposure to health care (i.e., exogenous infection) through the contaminated hands of health care providers, the environment, contaminated medical equipment, other patients, or visitors. A variety of factors can contribute to the development of health care–associated infections, and in many cases, these infections are multifactorial in nature. These factors can be related to the pathogen, the host, the specific health care interventions that a patient receives, the setting in which health care is received, and the methods by which these interventions are implemented. Health care–associated infection prevention strategies focus on eliminating, reducing, or modifying one or more of these risk factors.

Pathogen-Related Factors

The pathogen-related factors that contribute to the ability of an organism to cause infection include the organism's normal reservoir, mode of transmission (e.g., direct or indirect contact transmission, respiratory droplets, airborne particles), ability to survive on inanimate objects and surfaces, ability to produce biofilm, virulence factors, and resistance to antimicrobial agents or disinfectants.

Host-Related Factors

The host-specific factors that are associated with an inherent increased risk of one or more types of infection, regardless of the receipt of health care, include age (with older adults having an increased risk of infection because of senescence of the immune system), obesity, smoking, severity of illness, and certain comorbid conditions (e.g., burns [Chapter 97], end-stage liver [Chapter 140] or renal disease [Chapter 117], poorly controlled diabetes [Chapter 210], some cancers, congenital or acquired immune deficiency [Chapter 231]). These factors reflect suppression of the immune system or breaches of other normal host defense mechanisms. Whereas many of these factors are not amenable to intervention or cannot be effectively modified in the short term, interventions that address remediable risk factors (e.g., obesity, smoking, poorly controlled diabetes mellitus) have the potential to reduce the risk of health care–associated infection during future episodes of health care.

Health Care–Related Factors

Health care–related infection risk factors result from interventions that are intended to treat or otherwise provide benefit for a patient's existing medical conditions but that also introduce an increased risk of infection. These factors may disrupt normal host defenses or alter the patient's normal microbiota (Chapter 257). Health care–related risk factors include the use of invasive devices (e.g., intravascular catheters, urinary catheters, endotracheal tubes), surgical procedures, exposure to antibiotics, receipt of immunosuppressive medications, and prolonged hospitalization. Because each of these interventions poses at least some degree of increased risk of infection, the risk-to-benefit ratio of each intervention must frequently be reassessed so that patients are not exposed to unnecessary risk. For example, central venous catheters and indwelling urinary catheters are major risk factors for primary blood stream infection and urinary tract infection, respectively. In a patient who has a true medical need for one of these devices, the benefits of the catheter exceed the risk of infection. However, once the patient recovers from the condition that necessitated use of the catheter, the risks associated with the device then outweigh the benefits.

Exposure to antibiotics is a well-established risk factor for colonization and infection with multidrug-resistant organisms and development of *Clostridioides difficile* (Chapter 271) infection through a mechanism known as antibiotic selection pressure. Antimicrobial use is common in acute care hospitals and other health care settings, such as long-term care and dialysis facilities and ambulatory care practices. About one third of hospitalized European patients receive one or more antimicrobials during their hospital stay, as do about 50% of hospitalized patients in the United States.[2] The rate is even higher, over 70%, in surgical critical care units. Unfortunately, studies have shown that 25 to 75% of antimicrobial use in acute care, long-term care, and hemodialysis facilities is unnecessary or inappropriate because the regimen is broader in spectrum or longer in duration than necessary, the antibiotics do not provide activity against the causative pathogen, the patient does not actually have a bacterial infection (e.g., specimen contamination, asymptomatic colonization), or the prescribed dose is inappropriate. Misuse and overuse of antimicrobial agents in the outpatient setting are also well-recognized problems in the United States and other countries, including many countries where antimicrobials can be obtained without a prescription. This inappropriate use of antimicrobial agents introduces unnecessary risk for the development of complications of antibiotic therapy, including *C. difficile* infection, the emergence of multidrug-resistant organisms, and drug toxicity, and represents an important target for intervention.

Health Care Delivery–Related Factors

Health care delivery–related risk factors do not offer any potential benefit to patients but rather are associated only with risk. Such factors include but are not limited to failure to perform hand hygiene when indicated or to use aseptic or sterile technique during invasive procedures; unsafe injection practices (e.g., entering a multidose vial with a used needle); and failure to clean, disinfect, or sterilize the patient environment, medical equipment, and instruments. All these risks are potentially modifiable and are thus important targets for prevention initiatives. Antibiotic use, which is also a patient-specific health care–related risk factor, can also be considered a health care delivery–related risk factor because misuse of antibiotics in one patient or population can introduce risks among the larger population through changes in microbial ecology (i.e., selection and increased prevalence of antimicrobial-resistant pathogens).

Many of these health care delivery–related factors are the result of poor adherence to recommended, evidence-based infection prevention practices. Despite recognition that poor hand hygiene practice is a leading cause of pathogen transmission, the existence of major national and international guidelines, and initiatives to improve hand hygiene practices among health care providers, compliance with recommended hand hygiene practices among health care personnel remains unacceptably low.[3] In the United States, average rates of health care provider compliance with recommended hand hygiene practices have been reported to be less than 50%, with some individual studies reporting rates as low as 20% in some intensive care units (ICUs). Similarly, unsafe injection practices continue to be identified as the cause of health care–related transmission of blood-borne pathogens, such as hepatitis B and C viruses.

Environmental contamination can also contribute to the transmission of health care–associated pathogens.[4] For example, environmental contamination with *C. difficile* has been detected in up to 100% of hospital rooms occupied by patients with *C. difficile* infection, and methicillin-resistant *Staphylococcus aureus* (MRSA) has been detected on environmental surfaces in approximately 70% of hospital rooms housing patients infected and colonized with MRSA. Some, but not all, studies have identified similarly high rates of environmental contamination with multidrug-resistant gram-negative pathogens. This environmental contamination has been shown to result in patient-to-patient transmission through transient contamination of hands and equipment or by direct contact of the patient with the contaminated environment. Environmental contamination is, however, a potentially modifiable risk factor for health care–associated infection. Cleaning and disinfection of the environment and portable medical equipment that is shared among patients are often suboptimal. For example, one multicenter study conducted in 36 acute care hospitals in the United States found that at baseline, only 48% of high-risk environmental surfaces were cleaned during routine cleaning after discharge of the patient. Improvement in cleaning practices and other interventions to reduce the microbiologic burden in the health care environment can reduce the microbial burden of organisms in the environment and has been associated with a reduction in the risk of acquisition of multidrug-resistant organisms and *C. difficile* infection.[A1] Outbreaks of infection due to contaminated medical devices (e.g., duodenoscopes, heater-cooler devices used in cardiothoracic surgery procedures) highlight the critical role that cleaning, disinfection, and sterilization of medical equipment play in preventing health care–associated infections. In addition, environmental interventions are important to prevent patients from acquiring pathogens due to exposure to water (e.g., *Legionella* species; Chapter 290) and air (e.g., environmental fungi) within health care settings.

Pathogens in Health Care–Associated Infections

The organisms most commonly identified in device- and procedure-associated infections (i.e., central line–associated blood stream infection, catheter-associated urinary tract infection, ventilator-associated pneumonia, and surgical site infection) vary somewhat among the different types and sites of infection. Overall, in the United States 10 pathogen groups accounted for more than 75% of pathogens identified in device- and procedure-related infections reported to the CDC through the National Healthcare Safety Network between 2015 and 2017.[5] These pathogen groups and the proportion of reported pathogens that they represented include *Escherichia coli* (18%), *Staphylococcus aureus* (12%), *Klebsiella* species (9%), *Pseudomonas aeruginosa* (8%), *Enterococcus faecalis* (8%), coagulase-negative staphylococci (7%), *Enterobacter* species (5%), *Enterococcus faecium* (4%), *Proteus* species (3%), and *Candida albicans* (3%).

TABLE 261-2 RATES OF ANTIMICROBIAL RESISTANCE AMONG PATHOGENIC ISOLATES FROM HEALTH CARE–ASSOCIATED INFECTIONS

		PROPORTION OF ISOLATES RESISTANT TO ANTIBIOTIC		
ORGANISM	**ANTIBIOTIC CLASS**	***United States (2015-2017)****	***ICUs in 45 Asian, African, European, and Latin American Countries (2013-2018)**†*	***ICUs in 14 European Countries (2017)**‡*
Staphylococcus aureus	Anti-staphylococcal penicillins (e.g., oxacillin, methicillin)	44%	56%	24%
Klebsiella species	Extended-spectrum cephalosporins	19%	76-78%	40%
	Carbapenems	6%	49%	15%
Pseudomonas aeruginosa	Carbapenems	16%	53%	26%
Enterococcus faecium	Glycopeptides (vancomycin)	72%	29%	NR
Acinetobacter baumannii	Carbapenems	39%	92%	64%
Escherichia coli	Extended-spectrum cephalosporins	20%	66-68%	16%
	Carbapenems	0.7%	17%	0.8%
	Fluoroquinolones	36%	62%	NR

Multidrug-Resistant Bacteria

An increasingly concerning problem is the emergence of acquired antimicrobial resistance among many of the bacterial pathogens that are common causes of health care–associated infections (Table 261-2). Multidrug-resistant organisms represent a significant health threat because infections caused by many of these multidrug-resistant organisms have been associated with worse outcomes than those caused by antimicrobial-susceptible strains of the same organism, including excess length of hospital stay, increased health care costs, and higher mortality, with mortality rates approaching 50% in some studies.[6] Possible explanations for the observed increased rate of adverse outcomes associated with multidrug-resistant organism infections include the presence of more severe underlying disease, delays in initiating effective therapy, and the use of more toxic or less effective therapy for treatment of the infection. Regardless of their cause, the poor outcomes associated with multidrug-resistant organism infections highlight the critical need for effective preventive measures and development of new antibiotics with activity against them, particularly multidrug-resistant gram-negative bacilli.

Organisms can develop resistance to antimicrobial agents to which they were previously susceptible through a variety of mechanisms, including induction, genetic mutation, and acquisition of new genetic material (e.g., conjugation with cell-to-cell transfer of genetic material by plasmids or transposons). In health care settings, however, patient-to-patient transmission of multidrug-resistant organisms is more common than de novo development of resistance in a previously susceptible organism within the patient's existing microbiome. Identified risk factors for acquisition of multidrug-resistant organisms include exposure to antibiotics, frequent or prolonged exposure to health care facilities (e.g., hospitals, nursing homes), poor infection control practices among health care providers, environmental contamination with multidrug-resistant organisms, and prevalence of multidrug-resistant organisms among other patients within a health care facility.

Among the pathogens reported to the CDC between 2015 and 2017 as causes of device-associated infections and surgical site infections in adults, acquired antimicrobial resistance was relatively common (see Table 261-2). For example, 72% of *Enterococcus faecium* isolates were vancomycin resistant, and 44% of *S. aureus* isolates were resistant to methicillin (MRSA). Multidrug resistance among gram-negative pathogens also is a growing global health threat among persons receiving health care (Chapter 281). Approximately 10% of the most common gram-negative pathogens reported to the CDC in 2015-2017 demonstrated acquired resistance to at least one drug in three or more antibiotic classes. For example, 39% of *Acinetobacter baumannii* isolates, 11% of *Klebsiella* and *P. aeruginosa* isolates, and 9% of *E. coli* isolates met this definition of multidrug resistance.

Although the lack of a standardized definition of multidrug resistance limits direct comparisons of data from different populations, antimicrobial resistance is an important problem in many regions of the world. For example, International Nosocomial Infection Control Consortium data from device-associated infections in ICUs in 45 countries in Asia, Africa, Europe, and Latin America collected between 2013 and 2018 demonstrated methicillin resistance in 56% of *S. aureus* isolates, as well as carbapenem resistance in 49% of *Klebsiella* species isolates and 92% of *Acinetobacter* species isolates.

One example of the emergence and rapid dissemination of multidrug-resistant gram-negative bacilli is carbapenem-resistant Enterobacteriaceae, particularly *K. pneumoniae* (Chapter 281). In the United States, carbapenem resistance among the Enterobacterales is usually, but not always, due to the production of *K. pneumoniae* carbapenemase (KPC), a class A serine β-lactamase enzyme that hydrolyzes all β-lactam antibiotics. The *K. pneumonia* carbapenemase enzyme, which was first described in 2001, is encoded by the bla_{KPC} gene carried on a transmissible plasmid that also carries additional genes that confer resistance to several other classes of antimicrobial agents. Thus, in addition to carbapenem resistance, these organisms demonstrate resistance to other β-lactam antibiotics and to several other classes of antibiotics.

Asymptomatic carriage of multidrug-resistant organisms is relatively common among persons exposed to health care. In fact, patients with clinically apparent multidrug-resistant organism infections represent a relatively small proportion of the total burden of these pathogens. Reported rates of MRSA carriage have ranged from 4.6 to 13.6% among hospital patients, 2 to 22% among U.S. ambulatory dialysis patients, and 10 to 100% among residents of long-term care facilities. The prevalence of carriage of vancomycin-resistant enterococci among hospital patients and ambulatory dialysis patients has been reported to range from 6.3 to 67% and 0 to 16%, respectively. Studies that have included a variety of multidrug-resistant gram-negative bacilli have reported carriage rates of 19 to 32% in ICU patients and hospital patients with diarrhea, 25% among residents of long-term care facilities, and 16% among chronic hemodialysis patients. Studies that have focused specifically on carbapenem-resistant Enterobacterales have demonstrated prevalence rates ranging from 2 to 5.4% among high-risk hospital patients in the United States and 2 to 49% among post–acute care facility patients in Israel. These asymptomatic carriers play an important role in the epidemiology of multidrug-resistant organism infections. First, they represent a substantial risk of subsequent infection, with up to one third of carriers of MRSA, vancomycin-resistant enterococci, and multidrug-resistant gram-negative bacilli developing symptomatic infection within 12 months. Second, carriers of asymptomatic multidrug-resistant organisms can contribute to widespread transmission within the health care system through contamination of their surrounding environment. Several studies have demonstrated that the risk of acquiring a multidrug-resistant organism during hospitalization is related to the prevalence, or colonization pressure, of that multidrug-resistant organism among other patients. Finally, admission to a hospital room in which the prior patient was colonized or infected with MRSA, vancomycin-resistant enterococci, or multidrug-resistant gram-negative bacilli has been associated with an increased risk of acquisition of those organisms.

Over the past 15 to 20 years, encouraging data have shown a decline in the incidence of some multidrug-resistant organisms, particularly MRSA. In the United States, for example, the incidence of hospital-onset MRSA blood stream infections decreased by 74% between 2005 and 2016. These changes occurred despite the emergence of community-associated MRSA among persons without typical health care–associated risk factors and the introduction of community-associated MRSA as a health care–acquired pathogen.[7] In the United Kingdom, a 97% reduction in the number of cases of ICU-associated MRSA blood stream infection was reported through a mandatory reporting system between 2007 and 2016. In more recent years, however, the incidence of MRSA infections in hospitalized patients appears to have plateaued. The specific cause of these observed decreases in MRSA health care–associated infections is uncertain and may be the result of improvements in basic infection control practices, introduction of specific MRSA prevention practices, or other changes in the epidemiology of this pathogen.

Infection with *Clostridioides difficile*

C. difficile, the etiologic agent of pseudomembranous colitis, is the most common cause of health care–associated infectious diarrhea (Chapter 271). Although community-associated *C. difficile* infection occurs, the majority of cases are associated with receipt of health care. Clinical manifestations of *C. difficile* infection range from asymptomatic carriage to mild diarrhea to life-threatening colitis, toxic megacolon, and sepsis. The overall mortality associated with *C. difficile* infection has ranged from 2 to 6%. Compared with patients without *C. difficile* infection, hospital patients who develop *C. difficile* infection experience an extended duration of hospitalization, and approximately 15 to 30% of these patients will experience at least one recurrence of the disease, typically within 1 to 2 months of the initial episode. Between 2011 and 2017, the estimated U.S. national burden of health care–associated *C. difficile* infection decreased by 36%,[8] likely due to a reduced use of fluoroquinolones, diagnostic stewardship interventions, and increased adherence to recommended prevention practices. Despite this substantial reduction, the burden of health care-associated *C. difficile* infection remained high, with an estimated 235,000 cases occurring in 2017, and these numbers have remained relatively similar since then (Chapter 271).

The problem of *C. difficile* extends to chronic care facilities. About 20% of hospital-onset *C. difficile* infection occurs among persons with recent residence in a nursing home, and two thirds of nursing home–onset *C. difficile* infection cases occur among residents who have been recently discharged from an acute care hospital. Transmission in the health care setting can occur as the result of exposure to organisms on health care providers' hands, environmental surfaces, or medical equipment. In the absence of effective hand hygiene practices, contaminated health care providers may transmit the organism to other patients. Contamination of the environment and medical equipment with *C. difficile* is also common. Testing performed in hospital rooms has identified *C. difficile* on environmental surfaces in up to 100% of rooms housing patients with active *C. difficile* infection and in as many as 33% of non–*C. difficile* infection patient rooms. Commonly contaminated surfaces include bed rails, bedside tables, telephones, call buttons, and blood pressure cuffs. *C. difficile* spores are resistant to killing by many common hospital disinfectants and can persist in the environment for long periods of time, further contributing to the risk of exposure to a contaminated environment.

Although exposure to any antimicrobial agent may increase the risk for development of *C. difficile* infection, clindamycin, third-generation cephalosporins, penicillins, and fluoroquinolones may present the highest risk. Other factors that have been associated with an increased risk for development of *C. difficile* infection include receipt of cytotoxic chemotherapeutic agents and gastric acid suppressive medications such as proton pump inhibitors, failure to develop an antibody response to *C. difficile*, and older age (i.e., age older than 64 years).

Viruses

Respiratory Viruses

Common respiratory viruses, such as influenza (Chapter 332), can be transmitted in the health care setting by health care providers, visitors, and patients, thereby resulting in health care–acquired disease. Higher rates of morbidity and mortality have been observed among patients who acquire infection during hospitalization, probably owing to the presence of significant underlying medical illness. Several studies have associated higher influenza immunization rates among health care providers with lower rates of transmission of nosocomial influenza, thereby leading to efforts to increase influenza vaccination rates among health care providers. By the 2018-2019 influenza season, vaccination rates of 90% and 83.8% had been achieved among health care providers in acute care and long-term acute care hospitals in the United States. In addition to influenza, outbreaks of other respiratory virus infections for which vaccines are not available, such as respiratory syncytial virus (Chapter 330), continue to occur.

The health care–associated transmission of newly emerged respiratory viruses, such as the severe acute respiratory syndrome coronavirus (SARS-CoV; Chapter 334) in 2003, pandemic influenza in 2009, the Middle East respiratory syndrome coronavirus (MERS-CoV) in 2013, and especially SARS-CoV-2 (the cause of coronavirus disease 2019 [COVID-19; Chapter 336]) starting in 2019,[9] highlights the importance of surveillance to allow rapid identification of patients with potentially communicable diseases and implementation of appropriate infection control precautions.

Blood-borne Viruses

Although routine screening of the blood supply for the blood-borne pathogens hepatitis B virus, hepatitis C virus (Chapter 135), and human immunodeficiency virus (Chapter 353) has dramatically decreased the incidence of health care–associated blood-borne pathogen infections, transmission of these pathogens within health care settings continues to occur. Most health care–associated transmission of blood-borne pathogens is now due to failure to adhere to recommended basic infection control practices. Unsafe injection practices (e.g., reuse of syringes, contamination of multidose vials, improper use and disinfection of blood glucose monitoring devices that are used for multiple patients) and inadequate cleaning, disinfection, and sterilization of medical equipment and the health care environment (e.g., dialysis facilities) have been identified in several recent outbreaks of patient-to-patient transmission of blood-borne pathogens. A large proportion of documented health care–associated hepatitis B virus and hepatitis C virus transmission events has occurred in outpatient settings and long-term care facilities, thereby highlighting the importance of infection prevention programs throughout the entire health care system. Transmission of blood-borne pathogens from health care providers to patients is uncommon but can occur, typically in the setting of "exposure-prone" invasive procedures but also as a result of drug diversion by health care providers. Guidelines are available to assist health care providers and health care facilities in minimizing the risk posed to patients by blood-borne pathogen-infected health care providers while allowing most such providers to remain involved in patient care activities (E-Table 261-1).

Fungi

Candida albicans and other *Candida* species (Chapter 310) accounted for approximately 6% of all pathogens reported to the CDC between 2015 and 2017 as causes of device-associated infections and surgical site infections, thereby placing them among the most common pathogens implicated in health care–associated infections. The emergence of multidrug-resistant *C. auris* as a cause of health care facility–associated outbreaks further highlights the importance of *Candida* species in health care–associated infection epidemiology. Exposure to environmental fungi, such as *Aspergillus* species (Chapter 311), in the health care setting can result in health care–associated infection, particularly in immunocompromised hosts. Such exposure and resulting infection are most commonly associated with inadequate environmental control measures during construction, demolition, or water damage within the health care facility. A multistate outbreak of invasive fungal infections in the United States, mostly due to *Exserohilum rostratum* associated with contaminated methylprednisolone injections, demonstrated that contaminated medications and other medical products are additional potential sources of exposure to fungal pathogens during health care.

Device-Associated Infections

Central Line–Associated Blood Stream Infections

Central line–associated blood stream infections are blood stream infections that occur in patients who have a central venous catheter and in whom no other source of the infection is identified. Central line–associated blood stream infections are associated with longer hospital stays, increased risk of death, and greater hospital costs (see Table 261-1). Rates of morbidity and mortality, however, vary substantially, depending on the causative pathogen and characteristics of the patient in whom the infection occurs. Although central line–associated blood stream infections are often thought of as a complication that occurs among ICU patients, the use of central venous catheters in non-ICU hospital settings has expanded substantially, and the incidence and overall burden of central line–associated blood stream infections in some non-ICU settings now often exceeds that in ICUs. Central line–associated

blood stream infections are also important problems among nonhospitalized persons who have central venous catheters, such as patients receiving chronic total parenteral nutrition, chemotherapy, or dialysis in the outpatient or home care setting.

Blood stream infections due to central venous catheters are largely the result of contamination or colonization of the external surface or the intraluminal surface of the catheter. This contamination can occur either during or after insertion of the catheter. Effective strategies can reduce the risk of catheter contamination during insertion and throughout the time that the catheter remains in situ (see E-Table 261-1). The "central line bundle," which refers to evidence-based practices that, when used together, can reduce the risk of central line–associated blood stream infection even more than would be expected when the components are introduced individually, includes hand hygiene; maximal barrier precautions during insertion (i.e., use of sterile gown and gloves and a surgical cap and mask by the operator and covering the patient with a sterile, full-body drape); chlorhexidine skin antisepsis; optimal insertion site selection; and daily review of whether the catheter is necessary, with immediate removal if it is not. Randomized trials of cutaneous skin antisepsis prior to central venous catheter insertion show that a chlorhexidine-alcohol skin antiseptic solution provides greater protection against short-term catheter-related infections than does a povidone iodine–alcohol solution.[A2] Chlorhexidine-alcohol also leads to lower rates of infectious complications than does povidone-iodine when used for skin antisepsis for insertion of peripheral intravenous catheters.[A3] Other interventions that have been associated with reductions in central line–associated blood stream infection rates include covering of the insertion site with a sterile gauze or semipermeable transparent dressing, cleansing of the catheter insertion site with an antiseptic such as chlorhexidine, use of aseptic technique to access and to manipulate the catheter, scrubbing of the catheter hub with a disinfectant before accessing the catheter lumen for administration of medications or other products or for aspiration of blood, use of antimicrobial- or antiseptic-coated catheters, and use of chlorhexidine rather than regular soap and water for daily bathing of ICU patients. With these procedures, central venous and arterial infusion sets can be replaced every 7 days rather than every 4 days with equivalent safety.[A4] Widespread adoption of the central line bundle and other central line–associated blood stream infection prevention strategies has been associated with a 50% decrease in the incidence of central line–associated blood stream infection in U.S. hospitals between 2008 and 2016. These improvements appear to be continuing, with an additional 7% decrease observed between 2018 and 2019.

Catheter-Associated Urinary Tract Infections

A catheter-associated urinary tract infection (Chapter 263) is a urinary tract infection that develops in a patient who has or who recently had an indwelling urinary catheter. Similar to the pathogenesis of catheter-related blood stream infections, catheter-associated urinary tract infections develop by the introduction of pathogens into the bladder as a result of contamination and colonization of the internal or external surface of the catheter. Among patients with indwelling urinary catheters, the incidence of bacteriuria is 3 to 8% per day, and 10 to 25% of patients with bacteriuria will subsequently develop symptoms consistent with a urinary tract infection.

A number of basic practices, such as aseptic technique during insertion, maintenance of proper cleanliness and hygiene, securement of the catheter to avoid piston-like movement of the catheter within the urethra, and maintenance of a closed system with unobstructed flow of urine from the bladder into the collection system, are recommended to reduce the risk of catheter-associated urinary tract infection. It is estimated that by implementing such practices, 65 to 70% of catheter-associated urinary tract infections that occur in acute care hospitals can be prevented. Several studies have demonstrated that indwelling urethral catheters are often inserted for inappropriate reasons and that many catheters that were initially inserted for an appropriate indication remain in place even after the initial indication for catheterization has resolved. Additional studies found that physicians are often unaware that their patient has a urinary catheter. Thus, the greatest opportunity for catheter-associated urinary tract infection prevention is avoidance of unnecessary catheter insertion and prompt removal of catheters that are no longer necessary. Development of protocols that explicitly define appropriate indications for insertion of urinary catheters, introduction of interventions that remind clinicians to reassess the appropriateness of a patient's urinary catheter, and nurse-driven protocols that allow nurses to remove unnecessary urinary catheters have been associated with reduced use of urinary catheter and lower rates of catheter-associated urinary tract infection.

Ventilator-Associated Pneumonia

In hospitalized patients, mechanical ventilation (Chapter 91) is one of the most common risk factors for the development of pneumonia. Mechanical ventilation and the interventions required to provide mechanical ventilation (e.g., endotracheal intubation, sedation) increase the risk of pulmonary infection through a variety of mechanisms, including an increased risk of aspiration of oropharyngeal and gastrointestinal secretions and impairment of the cough reflex. From both a clinical and epidemiologic standpoint, ventilator-associated pneumonia (Chapter 85) is a difficult diagnosis to establish with certainty because of the subjective nature of many of the variables considered (e.g., chest radiographic findings, changes in the characteristics of respiratory tract secretions), alternative explanations for clinical and radiographic abnormalities (e.g., acute respiratory distress syndrome, atelectasis), and difficulty in determining whether the results of respiratory tract cultures represent true infection or colonization of the airway.

Pneumonia is the most common health care–associated infection in U.S. hospitals, and approximately 35% of cases are associated with mechanical ventilation. These infections are associated with mortality rates and health care costs that are among the highest observed among all health care–associated infections (see Table 261-1). Studies suggest that at least 55% of cases of ventilator-associated pneumonia are preventable. As with other device-associated infections, avoiding the use of the device is the most effective means to prevent infection. To prevent ventilator-associated pneumonia and other complications of mechanical ventilation, the use of noninvasive methods of ventilation, minimized use of sedation (e.g., manage patients without a sedative if possible, daily sedation interruption and assessment of readiness to be extubated), and early mobilization can eliminate or at least reduce the duration of mechanical ventilation (Chapter 91). For patients who do require mechanical ventilation, the following are routinely recommended to prevent ventilator-associated pneumonia: proper cleaning, disinfection, sterilization, use, and maintenance of respiratory equipment; minimizing pooling of secretions above the endotracheal tube cuff; and elevating the head of the bed (unless it is medically contraindicated). Chlorhexidine mouthwash or gel as part of oral hygiene care can reduce the incidence of ventilator-associated pneumonia by about 30%, but this reduction is due largely to the findings of unblinded studies, with double-blinded studies not demonstrating a clear benefit.[A5] For patients who are ventilated and treated with targeted hypothermia after out-of-hospital cardiac arrest (Chapter 50), 2 days of intravenous amoxicillin-clavulanate (at doses of 1 g and 200 mg, respectively) administered three times a day reduces the incidence of early ventilator-associated pneumonia by about 45%.[A6] In some randomized controlled trials, selective oropharyngeal or digestive decontamination has been associated with a significant reduction in ventilator-associated pneumonia, but this approach has not yet been widely adopted as a standard of care in the United States, at least in part because of concerns that it may lead to selection of antimicrobial-resistant organisms.

Other Device-Related Infections

With advances in medical technology, implantable devices are being used to treat and to manage a variety of medical conditions, particularly of the cardiovascular and nervous systems. These devices include cardiovascular implantable electronic devices such as pacemakers and implantable cardioverter-defibrillators (Chapter 54), ventricular assist devices (Chapter 46), deep brain stimulators, and intrathecal pumps. The potential benefits that these devices may offer to patients come with at least some degree of risk of device-related infection.

Surgical Site Infections

Surgical site infections are infections that develop at the site of an operative procedure. Although only a relatively small proportion of patients who undergo surgery subsequently develop a surgical site infection and the overall mortality rate is relatively low, the absolute number of surgical site infections that occur and the overall cost and burden of morbidity and mortality associated with them are large because of the volume of surgical procedures performed each year (see Table 261-1). A number of factors contribute to the risk of surgical site infection: the specific site and type of surgical procedure; duration of the procedure; tissue hypoxia at the surgical site; wound contamination with endogenous or exogenous organisms; surgical technique; perioperative infection prevention practices; environmental controls related to temperature, humidity, and air purity within the operating room; and the patient's underlying medical conditions, smoking status, and other factors that may increase the inherent risk of infection. Although some of these factors are not amenable

to corrective intervention, a number of interventions have been proven to reduce the risk of those that are.

An estimated 55% of surgical site infections could be prevented by routine application of evidence-based preventive measures. The use of sterile technique, preoperative skin preparation with an antiseptic agent,[A7] administration of antimicrobial prophylaxis within 60 minutes before the surgical incision, maintenance of normothermia, and perioperative glucose control have been demonstrated to reduce the risk of infection associated with a wide variety of surgical procedures. With such appropriate techniques, continuing antibiotic prophylaxis postoperatively does not appear to yield additional benefit for reducing surgical site infections.[A8] In some types of surgeries and some patients, the use of supplemental oxygen (e.g., 80% fraction of inspired oxygen) in the perioperative period may reduce the risk of surgical site infection. Although opportunities for improvement remain, surveillance data reported to the CDC's National Healthcare Safety Network by U.S. hospitals showed reductions in the incidence of surgical site infection occurring in association with 10 common surgical procedures from 2008 to 2017, but no further reductions since.[10]

PREVENTION

At least 55 to 70% of some of the most common health care–associated infections can be prevented. Scientific research and clinical experience have led to the publication of evidence-based guidelines for the prevention of health care–associated infections (see E-Table 261-1).[11] Strategies to prevent health care–associated infection are designed to interrupt one or more of the factors associated with pathogen transmission or the development of infection due to endogenous or exogenous organisms. Horizontal prevention strategies have the potential to prevent a wide variety of health care–associated infections or to prevent transmission of a variety of pathogens. Conversely, vertical strategies target a specific pathogen. Examples of horizontal prevention strategies include hand hygiene, education of health care providers, environmental cleaning and disinfection, antimicrobial stewardship, and use of aseptic technique for invasive procedures. Examples of vertical strategies include an influenza vaccination campaign or active surveillance testing to detect asymptomatic MRSA-infected carriers who may serve as unrecognized reservoirs for its transmission, followed by targeted decolonization therapy for persons identified as carriers.

Basic practices (e.g., most of the horizontal approaches described earlier plus a few vertical approaches, such as transmission-based precautions) should routinely be implemented in all health care facilities, whereas special or advanced interventions are added when basic practices fail to control or prevent health care–associated infections or transmission of one or more specific pathogens within the facility (see E-Table 261-1). The selection of specific strategies to be implemented within a specific health care facility should be based on an assessment of risk, local data and epidemiology, scientific evidence and guidelines, regulatory and accreditation requirements, and facility-specific cost-benefit calculations.

Antimicrobial Stewardship

Antimicrobial stewardship refers to interventions designed to improve the appropriateness of antimicrobial use by promoting the selection of an optimal antimicrobial regimen (i.e., the most appropriate drug, dose, duration, and route of administration) for a specific patient. The goals of an antimicrobial stewardship program are to optimize clinical outcomes (e.g., cure of infection related to antimicrobial use, minimize toxicity and other adverse events) but also to limit the antimicrobial selection pressure that drives the emergence of antimicrobial-resistant strains. Multidisciplinary antimicrobial stewardship programs have been associated with several desirable outcomes, including significant reductions in antimicrobial use, reduced rates of antimicrobial resistance among health care–associated pathogens, reduced incidence of adverse outcomes associated with antibiotic use (e.g., toxicity, *C. difficile* infection), improved clinical outcomes, and significant reductions in hospital antimicrobial-associated costs.

A variety of approaches have been used by successful antimicrobial stewardship programs (see E-Table 261-1).[12] One of the most commonly used and most effective strategies includes formulary restriction and requirement of preauthorization before prescribing certain antibiotics (e.g., antibiotics that are broad in their antimicrobial spectrum, are associated with significant toxicity, or are expensive). A second core strategy is a prospective audit of the appropriateness of prescribed antimicrobial therapy, with provision of feedback to the prescribing clinician if opportunities for further optimization of therapy are available (e.g., narrowing or broadening spectrum of therapy, discontinuing antimicrobial therapy, or altering drug dose or dosing interval on the basis of available clinical data). Additional approaches include education, development of guidelines and clinical pathways, computer-assisted decision support, and protocols to optimize conversion from the parenteral to the oral route of administration when appropriate. In general, using more stewardship programs reduces the overuse of antibiotics.[13] Antimicrobial stewardship programs must also address the complex and constantly changing problems and issues associated with antimicrobial resistance.

Decolonization Therapy

Decolonization refers to the administration or application of antimicrobial or antiseptic agents to a person to eliminate or to reduce the burden of carriage of one or more pathogens. Data on decolonization are promising but inconsistent, thereby suggesting that factors such as compliance and bathing technique as well as patient- and hospital-specific factors may influence the outcomes observed at the individual hospital and patient levels.

For example, selective oropharyngeal and digestive decontamination can prevent ventilator-associated pneumonia and surgical site infections after colorectal surgery. Selective digestive tract decontamination can potentially reduce in-hospital mortality among ICU patients who are receiving mechanical ventilation,[A9] but it is associated with a more pronounced increase in carriage of aminoglycoside-resistant gram-negative bacteria, thereby raising concerns about long-term risk of antimicrobial resistance.

Topical decolonization therapy, with or without systemic antibiotic therapy, can suppress or eradicate *S. aureus* among known carriers, thereby reducing the risk of infection for themselves and others. Universal decolonization with intranasal mupirocin for 5 days in addition to daily chlorhexidine bathing can significantly reduce MRSA-positive clinical cultures and blood stream infections due to any pathogen in ICU patients. In patients who are hospitalized in non–critical care units, daily bathing with chlorhexidine plus 5 days of intranasal mupirocin is not beneficial overall[A10] but does appear to be beneficial specifically for patients who have medical devices (e.g., central venous catheters, midline catheters, or lumbar drains). In patients who are colonized with MRSA, targeted treatment with chlorhexidine mouthwash, chlorhexidine baths or showers, and intranasal mupirocin for 5 days twice per month for 6 months after hospital discharge reduces MRSA infection by about 30% compared with routine hygiene education alone.[A11]

Daily bathing with chlorhexidine, rather than non-antimicrobial soap, without the use of intranasal mupirocin has had mixed results. For example, a single-site study showed no benefit for reducing the incidence of health care–associated infections in adult ICU patients,[A12] whereas a trial in eight adult ICUs and one bone marrow transplant unit found that daily bathing with chlorhexidine was associated with a 23% reduction in the combined outcome of MRSA and vancomycin-resistant enterococci acquisition. Another single-site randomized trial also showed every other day bathing with chlorhexidine was associated with a significant reduction in hospital-acquired infections.[A13] Although the precise role for decontamination therapy remains uncertain, its use has become fairly common in ICU settings and it has been incorporated into some clinical guidelines for the prevention of health care–associated infections, such as central line–associated blood stream infections.

Active Surveillance Testing

Active surveillance testing identifies asymptomatic carriers of a pathogen of interest (e.g., MRSA, vancomycin-resistant enterococci, multidrug-resistant gram-negative bacilli) with the intention to introduce additional interventions for identified carriers to prevent infection in the carrier or transmission to others. The interventions that may be applied to the identified carriers include transmission-based precautions (e.g., contact precautions), decolonization therapy (mostly applicable to *S. aureus*), and altered antimicrobial therapy (e.g., surgical antimicrobial prophylaxis). Active surveillance is commonly used in conjunction with other interventions to control outbreaks. In the nonoutbreak setting, numerous reports suggest that active surveillance as part of a comprehensive program can reduce infection with multidrug-resistant organisms in individual hospitals, large hospital systems, and health care facilities within specific geographic regions, such as a number of Northern European countries. However, a U.S. trial found no significant difference in the incidence of colonization or infection with MRSA and vancomycin-resistant enterococci in ICUs that performed active surveillance testing with introduction of contact precautions for patients found to be carriers of MRSA or vancomycin-resistant enterococci compared with ICUs that did not conduct active surveillance testing.

Routine use of gowns and gloves for all patients is another intervention that has potential for reducing the risk of transmission of pathogens among patients by reducing contamination of health care workers' hands and clothing.

A cluster-randomized study found that universal use of gowns and gloves for all patients in ICUs did not reduce the primary outcome of acquisition of either MRSA or vancomycin-resistant enterococci, but did significantly lower the acquisition of MRSA. Thus, the utility of this strategy for preventing pathogen transmission remains uncertain.

Interfacility and Regional Collaboration

Given the frequency with which patients are shared among hospitals and other health care settings within geographic regions and the evidence of interfacility patient transfer as a risk factor of introduction of multidrug-resistant organisms and *C. difficile* into a health care facility, implementation of comprehensive prevention programs in all facilities within a region may be more effective in preventing health care–associated infections and multidrug-resistant organism transmission than implementation of the same interventions in a single health care institution. The establishment of regional infection prevention initiatives offers several potential benefits, including the ability to address the complex epidemiology of health care–associated infections that involve multiple health care facilities (e.g., multidrug-resistant organism acquisition, transmission, and infection) than single-institution interventions and opportunities for collaboration and sharing of information, experiences, and resources. A number of successful regional and national initiatives for the prevention of health care–associated infection, including central line–associated blood stream infection, dialysis-related blood stream infections, MRSA, vancomycin-resistant enterococci, carbapenem-resistant Enterobacteriales, and *C. difficile*, have been described.

Incentives and Penalties

The Centers for Medicare and Medicaid Services Conditions of Participation list specific requirements for infection prevention and control processes in health care facilities that receive its funding. Hospitals found to be deficient in the implementation of the requirements are at risk of losing the funding that they receive from the agency. Similarly, hospital accreditation agencies such as The Joint Commission have established standards for infection prevention programs and periodically survey hospitals to determine if such programs are in place. In addition, public reporting of hospital-specific health care–associated infection data by the Centers for Medicare and Medicaid Services and other agencies, as well as the inclusion of health care–associated infection data in federal pay-for-performance programs, provides further incentives for hospitals to optimize their health care–associated infection prevention efforts.

262 APPROACH TO THE PATIENT WITH SUSPECTED ENTERIC INFECTION

JAMES M. FLECKENSTEIN

DEFINITION

Enteric infections are endemic in many low-income countries but may also be contracted from contaminated food or water in developed countries. Symptoms may range from minimal gastrointestinal distress to life-threatening watery diarrhea or dysentery.

EPIDEMIOLOGY

Worldwide, enteric infections are a leading cause of morbidity. In low- and middle-income countries without access to clean water and basic sanitation, young children are disproportionately affected with acute diarrheal illness and suffer sequelae ranging from malnutrition (Chapter 197) and its complications to dehydration and death. Although infrequently fatal in industrialized regions, enteric infections are ubiquitous ailments with pathogens that know no borders because of international travel to and from hyperendemic regions, as well as the globalization of food supplies. Foodborne outbreaks remain common in the United States, where pathogens are distributed widely in produce or other foods. For example, one of the largest outbreaks of *Salmonella enteritidis*, estimated to involve more than 200,000 people in the United States, resulted from national distribution of contaminated ice cream. Fortunately, many outbreaks can be mitigated when pathogens that are isolated from individual patients undergo molecular profiling by public health laboratories linked to the U.S. Centers for Disease Control and Prevention (CDC).

Etiology

Norovirus is the leading cause of infectious diarrhea in adults worldwide[1] and of enteric infection outbreaks in the United States,[2] but multiple microbial agents can cause enteric infections. Fortunately, the geographic location, exposure history, and clinical presentation often can refine the list of potential causative agents (Table 262-1).[3] For example, a patient who has recently returned from travel to a low-income country with acute watery diarrhea will likely be infected with one of several pathogens associated with traveler's diarrhea (Chapter 265),[4] particularly enterotoxigenic *E. coli*, whereas the onset of bloody diarrhea following consumption of poorly cooked ground beef is likely due to Shiga toxin–producing *E. coli* (Chapter 280). However, it is important to recognize that neither the pathogens nor their epidemiologic associations are static. The dynamic nature of the causes of outbreaks of acute enteric infections is demonstrated by the emergence and international spread of a multidrug-resistant *Shigella* strain (Chapter 285), as well as by a large European outbreak caused by a novel *E. coli* strain that had contaminated raw sprouts and acquired the ability to produce Shiga toxin (Chapter 280).

PATHOBIOLOGY

Enteric infections ultimately reflect the successful interaction of individual pathogens with their human hosts. Pathogens must overcome innate and acquired host defenses while competing with the normal human microbiota to colonize intestinal epithelia. Once established, pathogens may then elaborate toxins or produce virulence factors that promote adhesion and invasion.

Not all hosts are equally susceptible to enteric infections. The use of acid-blocking agents, such as proton pump inhibitors, impairs an important first line of host defense by decreasing gastric acidity, thereby reducing the effective

262 APPROACH TO THE PATIENT WITH SUSPECTED ENTERIC INFECTION

JAMES M. FLECKENSTEIN

DEFINITION

Enteric infections are endemic in many low-income countries but may also be contracted from contaminated food or water in developed countries. Symptoms may range from minimal gastrointestinal distress to life-threatening watery diarrhea or dysentery.

EPIDEMIOLOGY

Worldwide, enteric infections are a leading cause of morbidity. In low- and middle-income countries without access to clean water and basic sanitation, young children are disproportionately affected with acute diarrheal illness and suffer sequelae ranging from malnutrition (Chapter 197) and its complications to dehydration and death. Although infrequently fatal in industrialized regions, enteric infections are ubiquitous ailments with pathogens that know no borders because of international travel to and from hyperendemic regions, as well as the globalization of food supplies. Foodborne outbreaks remain common in the United States, where pathogens are distributed widely in produce or other foods. For example, one of the largest outbreaks of *Salmonella enteritidis*, estimated to involve more than 200,000 people in the United States, resulted from national distribution of contaminated ice cream. Fortunately, many outbreaks can be mitigated when pathogens that are isolated from individual patients undergo molecular profiling by public health laboratories linked to the U.S. Centers for Disease Control and Prevention (CDC).

Etiology

Norovirus is the leading cause of infectious diarrhea in adults worldwide[1] and of enteric infection outbreaks in the United States,[2] but multiple microbial agents can cause enteric infections. Fortunately, the geographic location, exposure history, and clinical presentation often can refine the list of potential causative agents (Table 262-1).[3] For example, a patient who has recently returned from travel to a low-income country with acute watery diarrhea will likely be infected with one of several pathogens associated with traveler's diarrhea (Chapter 265),[4] particularly enterotoxigenic *E. coli*, whereas the onset of bloody diarrhea following consumption of poorly cooked ground beef is likely due to Shiga toxin–producing *E. coli* (Chapter 280). However, it is important to recognize that neither the pathogens nor their epidemiologic associations are static. The dynamic nature of the causes of outbreaks of acute enteric infections is demonstrated by the emergence and international spread of a multidrug-resistant *Shigella* strain (Chapter 285), as well as by a large European outbreak caused by a novel *E. coli* strain that had contaminated raw sprouts and acquired the ability to produce Shiga toxin (Chapter 280).

PATHOBIOLOGY

Enteric infections ultimately reflect the successful interaction of individual pathogens with their human hosts. Pathogens must overcome innate and acquired host defenses while competing with the normal human microbiota to colonize intestinal epithelia. Once established, pathogens may then elaborate toxins or produce virulence factors that promote adhesion and invasion.

Not all hosts are equally susceptible to enteric infections. The use of acid-blocking agents, such as proton pump inhibitors, impairs an important first line of host defense by decreasing gastric acidity, thereby reducing the effective

ABSTRACT

Enteric infections may manifest as gastroenteritis, secretory diarrhea, bloody diarrhea, or enteric fever. The major cause of foodborne gastroenteritis worldwide is norovirus, but a variety of other viruses, enteric bacteria, and parasites can cause clinical disease. The most common cause of traveler's diarrhea is enterotoxigenic *Escherichia coli*. Bloody or mucoid stools, fever, and cramping abdominal pain should prompt cultures to identify *Shigella*, *Salmonella*, *Campylobacter*, Shiga toxin–producing *E. coli*, and *Yersinia* species. Molecular testing can frequently identify the infectious agent but not its antimicrobial susceptibility. Oral rehydration therapy and antidiarrheal agents are preferred for afebrile patients without bloody stools or severe dehydration, with antibiotic therapy recommended for more severe cases and for traveler's diarrhea when testing is not practical.

infectious diarrhea
norovirus

TABLE 262-1 EPIDEMIOLOGY, UNDERLYING CONDITIONS, AND EXPOSURE HISTORIES RELEVANT TO POTENTIAL ETIOLOGY OF INFECTION

EXPOSURE	LIKELY PATHOGEN(S)
Travel to low- or middle-income countries	Diarrheagenic *E. coli* (ETEC, EAEC, EPEC; Chapter 280), norovirus (Chapter 350), *Campylobacter* (Chapter 279), *Shigella* (Chapter 285), nontyphoidal *Salmonella* (Chapter 284), *Giardia* (Chapter 322), *Cryptosporidia* (Chapter 321), *Entamoeba histolytica* (Chapter 323), *Cyclospora* spp. (Chapter 324), rarely *V. cholerae* (Chapter 278), *Balantidium coli* (Chapter 324).
Daycare	Low-inocula pathogens: Shiga toxin–producing *E. coli* (STEC; Chapter 280), *Shigella* (Chapter 285), *Giardia* (Chapter 322), *Cryptosporidia* (Chapter 321), norovirus (Chapter 350), rotavirus (Chapter 350)
Prior antibiotic use	*Clostridioides difficile* (Chapter 271)
Immunosuppression, including AIDS	Cytomegalovirus (Chapter 347), *Cryptosporidia* (Chapter 321), *Cytoisospora belli* (Chapter 324), *Herpes simplex* virus (Chapter 345), *Mycobacterium avium* complex (Chapter 300), *Histoplasma* (Chapter 308), microsporidia (Chapter 324)
Long-term care, prisons	*C. difficile* (Chapter 271), norovirus (Chapter 350), *Shigella* (Chapter 285), rotavirus (Chapter 350), STEC (Chapter 280), *Giardia* (Chapter 322)
Pet reptiles	*Salmonella* spp. (Chapter 284)
Petting farms, pets	STEC, *Campylobacter* (Chapter 279), *Cryptosporidia* (Chapter 321), *Yersinia* (Chapter 288)
Pigs/pig feces	*Yersinia enterocolitica* (Chapter 288), *Balantidium coli* (Chapter 324)
Hemochromatosis	*Yersinia enterocolitica* (Chapter 288)
Raw shellfish	*Vibrio* spp. (Chapter 278), norovirus (Chapter 350), *Plesiomonas shigelloides* (Chapter 126)
Cruise ship travel	Commonly norovirus (Chapter 350), occasionally ETEC (Chapter 280)
Consumption of untreated fresh water, mountain areas of the United States	*Giardia* (Chapter 322)
Imported fresh produce (particularly raspberries), travel to tropical/semitropical regions	*Cyclospora* spp. (Chapter 324)
Swimming in public pools, waterparks	*Cryptosporidia* (Chapter 321)
Anal contact	*Shigella*, including MDR spp. (Chapter 285); other pathogens such as *E. histolytica* (Chapter 323) spread via fecal-oral contact

AIDS = acquired immunodeficiency syndrome; EAEC = enteroaggregative *E. coli;* EPEC = enteropathogenic *E. coli*; ETEC = enterotoxigenic *E. coli;* MDR = multidrug resistant; STEC = Shiga toxin–producing *E. coli.*

TABLE 262-2 CLINICAL FEATURES OF ENTERIC INFECTIONS

CLINICAL SYNDROME	POTENTIAL PATHOGENIC AGENTS	NOTES
Acute watery diarrhea	Diarrheagenic *E. coli* (Chapter 280), *V. cholerae* (Chapter 278), *Shigella* (Chapter 285), *Salmonella* (Chapter 284), *Campylobacter* (Chapter 279), norovirus (Chapter 350)	Severe cholera-like diarrhea leading to rapid dehydration can be associated with ETEC as well as *V. cholerae* infection.
Bloody diarrhea or passage of multiple small-volume stools with blood/mucus (dysentery)	STEC (Chapter 280), *Shigella* (Chapter 285), *Campylobacter* (Chapter 279), *Entamoebae histolytica* (Chapter 323), *Yersinia enterocolitica* (Chapter 288), noncholera *Vibrio* spp. (Chapter 278), *Salmonella* (Chapter 284), *Plesiomonas shigelloides* (Chapter 126), *Balantidium coli* (Chapter 324)	STEC may progress from acute watery diarrhea to bloody diarrhea over several days.
Predominant vomiting (gastroenteritis)	Norovirus (Chapter 350), preformed enterotoxin syndromes (*Bacillus cereus* [Chapter 272], *Staphylococcus aureus* [Chapter 267])	Preformed toxins typically cause disease with very short incubation periods (within hours of ingestion). Noroviral infections typically resolve within 48-72 hours.
Protracted diarrhea >2 weeks	Giardia (Chapter 322) and other protozoa, occasionally persistent bacterial infections (e.g., EAEC, EPEC, ETEC; Chapter 280), norovirus (Chapter 350) in immunocompromised hosts, helminths (Chapters 326 and 327)	Post-infection syndromes, including irritable bowel syndrome and tropical sprue (Chapter 126), should be considered in the absence of evidence of sustained infection. Brainerd diarrhea, an unexplained but presumably infectious syndrome of protracted diarrhea that follows ingestion of raw milk or untreated water, can cause diarrhea that persists for weeks to months. ETEC can cause illness for >2 weeks.
Acute febrile syndrome	*Listeria monocytogenes* (Chapter 272), *Campylobacter* (Chapter 279), nontyphoidal *Salmonella* (Chapter 284), *Yersinia enterocolitica* (Chapter 288)	Older adults may exhibit fewer symptoms
Predominant febrile illness, abdominal pain	Invasive nontyphoidal *Salmonella* (Chapter 284), enteric fever (Chapter 284)	Enteric fever refers to infections with *Salmonella enterica* serotype Typhi or *S. enterica* serotypes Paratyphi A-C

EAEC = enteroaggregative *Escherichia coli*; EPEC = enteropathogenic *Escherichia coli*; ETEC = enterotoxigenic *Escherichia coli*; STEC = Shiga toxin–producing *Escherichia coli.*

inocula required for bacterial pathogens. Recent prior or concurrent use of antibiotics can alter the normal intestinal microflora, thereby reducing its ability to impair the growth of newly introduced pathogens. Host genetics can also play critical roles in determining the outcome of infection. For instance, *Vibrio cholerae* infections (Chapter 278) tend to be most severe in individuals with O blood group, likely due to more efficient intoxication of O enterocytes with cholera toxin. In contrast, enterotoxigenic *E. coli* infections (Chapter 280) appear to be more severe in individuals who express the A blood group antigen on intestinal epithelia, likely due to an A-specific lectin expressed by these bacteria.

Some pathogens, particularly norovirus (Chapter 350), *Shigella* (Chapter 285), and *Shiga* toxin–producing *E. coli* (Chapter 280), typically require very low inocula to establish infection. This characteristic has contributed to numerous outbreaks of norovirus on cruise ships and a multitude of foodborne outbreaks of Shiga toxin–producing *E. coli* (Chapter 280).

CLINICAL MANIFESTATIONS

Enteric infections can be categorized by the acute clinical presentation (Table 262-2) and/or the associated sequelae that follow the initial infection.

Significant overlap exists in the initial presentation of illness caused by individual pathogens, and essentially all enteric pathogens can initially present with watery diarrheal illness. Progression to bloody diarrhea argues against a viral cause and instead should prompt investigation for invasive bacterial pathogens (e.g., *Shigella* [Chapter 285], Salmonella [Chapter 284], *Yersinia* [Chapter 288], *Campylobacter* [Chapter 279], Shiga toxin–producing *E. coli* [Chapter 280], or amebiasis [Chapter 323]).[5–7] Most patients with Shiga toxin–producing *E. coli* infection will progress to bloody diarrhea within days of onset of diarrhea, and as many as 15% will develop the hemolytic uremic syndrome (Chapter 158).

Vomiting as a predominant symptom suggests organisms typically associated with gastroenteritis, particularly norovirus (Chapter 350) and the syndromes associated with *Staphylococcus aureus* (Chapter 267) and *Bacillus cereus* (Chapter 272) preformed enterotoxins. The latter typically occur after a short incubation period within minutes to hours on the day of ingestion.

Oftentimes, the initial diarrheal episode is self-limited and may not come to the attention of a physician, who may later evaluate the patient for the first time following development of complications related to their infection. These complications may occur while the patient still has gastrointestinal symptoms or after the symptoms have resolved and organisms have disappeared from the stool (Table 262-3).

TABLE 262-3 COMPLICATIONS AND SEQUELAE OF ENTERIC INFECTIONS

SYNDROME	PREDISPOSITION/ASSOCIATED PATHOGEN(S)
Hemolytic uremic syndrome (Chapter 158)	STEC (Chapter 280), occasionally *Shigella dysenteriae* (Chapter 285)
Guillain-Barré syndrome (Chapter 388)	*Campylobacter jejuni* (Chapter 279)
Tropical sprue (Chapter 126)	Typically, in expatriates or those with extended stays in low- to middle-income countries following repeated episodes of diarrhea; unknown/ETEC? (Chapter 280)
Irritable bowel syndrome (Chapter 123)	*Campylobacter* (Chapter 279), *Salmonella* (Chapter 284), *Shigella* (Chapter 285), STEC (Chapter 280), post-traveler's diarrhea (Chapter 265)
Environmental enteropathy (environmental enteric dysfunction)	Children in low- and middle-income countries following *Shigella* (Chapter 285) and ETEC (Chapter 280) infections
Bacteremia, metastatic extraintestinal infection	*Salmonella typhi* and nontyphoidal *Salmonella* spp. (Chapter 284), *Campylobacter* (Chapter 279), *Yersinia* (Chapter 288), *E. histolytica* (Chapter 323)
Intestinal perforation, peritonitis, toxic megacolon	Small intestine, particularly terminal ileum with enteric fever (Chapter 284); *Shigella* (particularly *dysenteriae*) (Chapter 285); *C. difficile* (Chapter 271); *E. histolytica* (Chapter 323); *Balantidium coli* (colon; Chapter 324); *Yersinia* (Chapter 288); rarely *Campylobacter* spp. (Chapter 279)
Pseudoappendicitis (Chapter 128)	*Yersinia pseudotuberculosis* (Chapter 288), *Y. enterocolitica* (Chapter 288)
Reactive arthritis (Chapter 244)/ erythema nodosum	*Campylobacter* (Chapter 279), *Shigella* (Chapter 285), *Yersinia* (Chapter 288), *Salmonella* (Chapter 284)
Meningitis (Chapter 381)	*Listeria* (Chapter 272), *Salmonella* spp. (Chapter 284) in young children

ETEC = enterotoxigenic *Escherichia coli*; STEC = Shiga toxin–producing *Escherichia coli*.

DIAGNOSIS

General Approach

In most circumstances, an acute episode of diarrhea resolves spontaneously before a patient contacts a physician. When a patient does contact a physician, the first diagnostic decision is whether further evaluation is necessary.

Patients who have more severe forms of illness, such as fever, bloody diarrhea, systemic signs of infection, or protracted symptoms, will likely benefit from a specific diagnosis that can direct treatment. For example, bloody diarrhea caused by *Shigella* or amebic dysentery may benefit from antibiotic therapy, whereas antibiotics should not be used in Shiga toxin–producing *E. coli* infections, because they can increase the risk and severity of hemolytic uremic syndrome by accelerating the production of toxin.

Nearly all acute diarrheas are caused by contaminated food or water. Other than diarrhea due to parasitic infection, diarrhea that persists for a month or more is very unlikely to be infectious.

Laboratory Evaluation

Culture-independent molecular stool testing is emerging as a useful diagnostic approach because of its rapidity and ability to diagnose bacterial, viral, and protozoal infection[8,9] and thereby to guide whether empiric antimicrobial therapy is likely to be beneficial. However, these molecular tests do not provide sensitivity data to guide the choice among antibiotics or preserve the organism for subsequent outbreak investigations. In patients who have bloody or mucoid stool, severe diarrhea, or fever, routine stool culture is indicated (Table 262-4; Fig. 262-1) to obtain sensitivity data. Although microscopic stool examination

TABLE 262-4 STUDIES APPLICABLE TO DIAGNOSIS OF ENTERIC INFECTION

DIAGNOSTIC STUDIES	INDICATIONS	COMMENTS
Culture-independent molecular diagnostic tests	Syndromic diagnosis of diarrheal illness	Pros: can potentially detect pathogens that are difficult to diagnose in some clinical microbiology laboratories (e.g., *E. coli* diarrheal pathovars, parasites, and viruses). Cons: fail to preserve isolate for resistance testing or epidemic investigation.
Stool cultures	Bloody mucoid or moderate-severe diarrhea, fever	Most laboratories routinely test only for *Shigella*, *Salmonella*, *Campylobacter*, and STEC. Special culture media are needed for O157:H7 STEC, whereas other STEC require molecular and/or toxin assays. Other *E. coli* pathovars (ETEC, EPEC, EAEC) can be identified only by molecular diagnostics. Chromogenic media are available to distinguish *V. cholerae* and *V. parahaemolyticus* spp.
Blood cultures	Signs of systemic infection, extremes of age, immunocompromised hosts, travel to areas endemic for enteric fever	Sensitivity may be impacted by prior antibiotic use and sample volume.
Ova and parasite examination: (1) Trichrome staining (2) Modified acid-fast staining (*Cyclospora*, *Cystoisospora*, *Cryptosporidia*) (3) EIA for *Giardia*, *Cryptosporidia*	Persistent diarrhea, travel, or other risk factors	As oocyst passage can be intermittent and sparse ≥ 3 specimens collected every other day may be needed. Enterotest string sampling of small intestinal fluid or upper endoscopy with biopsy can be helpful in *Giardia* and other parasitic infections when stool burden is low.
C. difficile toxin A/B testing	Prior antibiotics, chemotherapy, hospitalization	Nucleic acid amplification tests are comparable in sensitivity to "gold standard" toxin neutralization/cytotoxicity assays but also may detect asymptomatic carriage, so they should be used in conjunction with toxin A/B EIA and/or EIA for glutamate dehydrogenase.

EAEC = enteroaggregative *Escherichia coli*; EIA = enzyme immunoassay; EPEC = enteropathogenic *Escherichia coli*; ETEC = enterotoxigenic *Escherichia coli*; STEC = Shiga toxin–producing *Escherichia coli*.

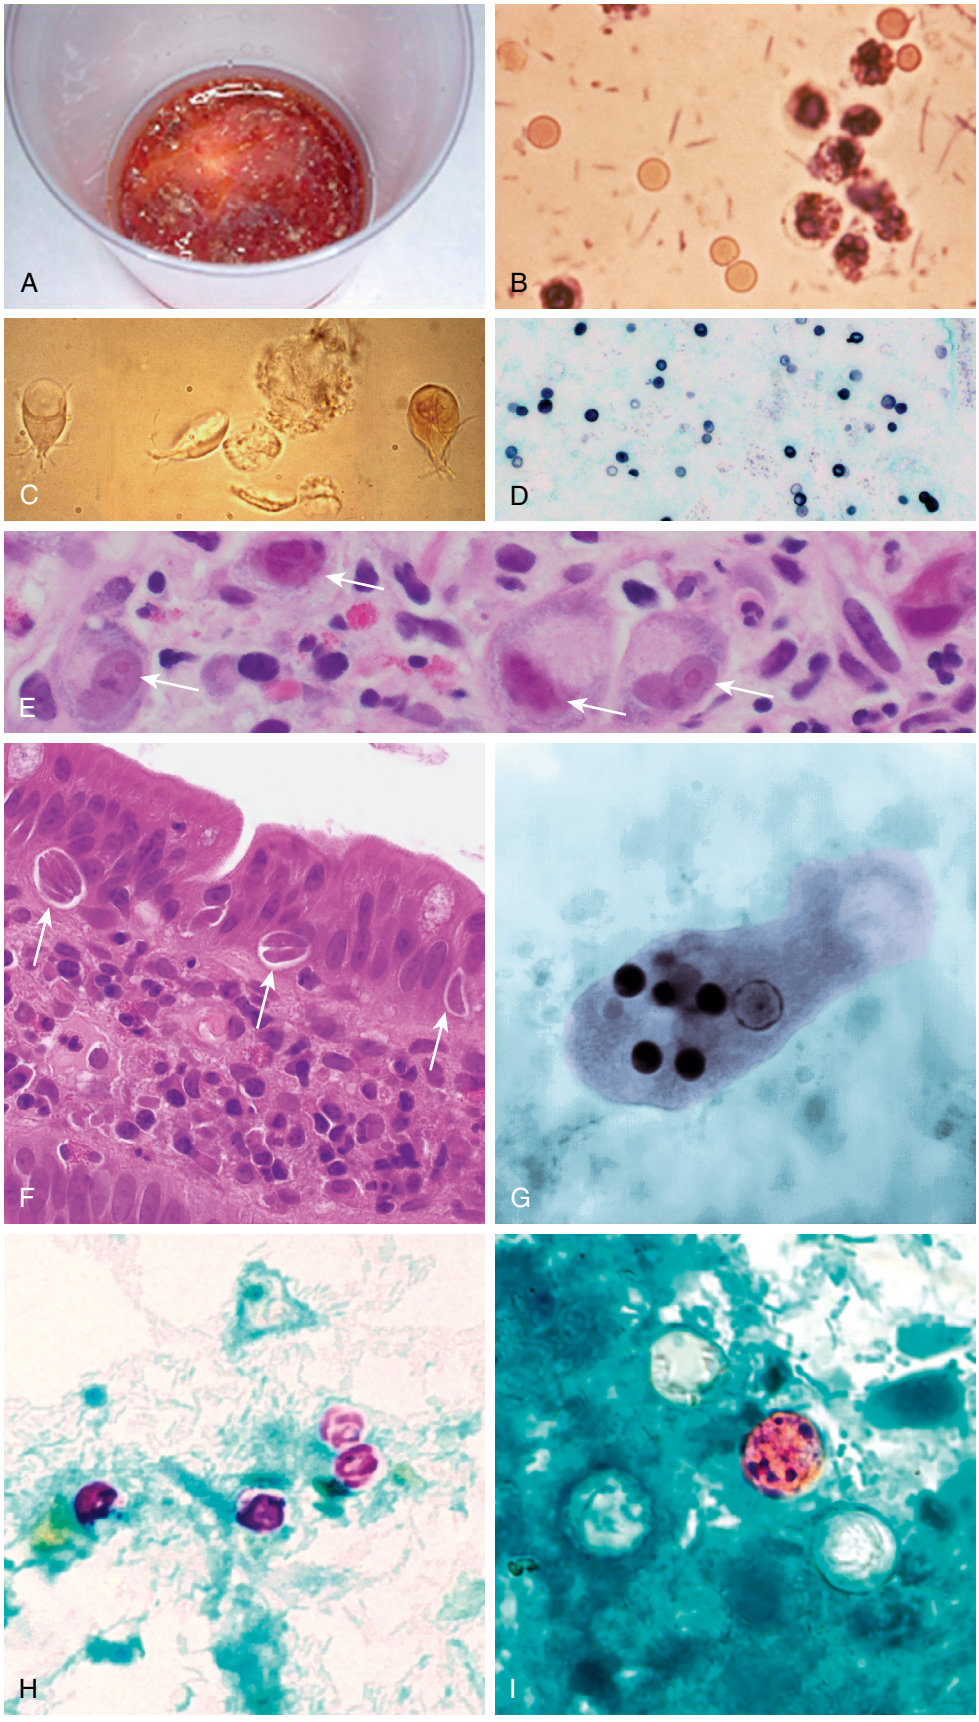

FIGURE 262-1. **Stool evaluation. A,** Dysenteric stool. **B,** Fecal leukocytes and erythrocytes in *Shigella* dysentery. **C,** *Giardia* trophozoites in small intestinal aspirate (iodine stain). **D,** Histoplasma in duodenal biopsy specimen. **E,** Cytomegalovirus-infected cells with typical "owl's eye" inclusion bodies. **F,** *Cystoisospora* oocysts in duodenal enterocytes. **G,** *Entamoeba histolytica* trophozoite with ingested erythrocytes (trichrome). **H,** *Cryptosporidium* oocyst (modified acid-fast). **I,** *Cyclospora* oocyst. (B, C, G, H, and I from the Centers for Disease Control and Prevention Public Health Image Library: https://phil.cdc.gov/default.aspx; D, E, and F courtesy of Drs. Kathleen Byrnes and Samuel Ballentine, Washington University in Saint Louis School of Medicine.)

can detect white blood cells, rapid molecular testing has diminished its utility. In patients who have persistent diarrhea especially related to travel, the stool should be examined microscopically for ova and parasites. Some infections, including cytomegalovirus (Chapter 347), histoplasmosis (Chapter 308), and protozoal infections, can be diagnosed by their appearance on intestinal biopsy specimens, which typically are obtained only in patients who have protracted cases of diarrhea or in patients who have underlying immunosuppression when neither molecular testing nor examination for ova and parasites reveals an etiology.

TABLE 262-5 TREATMENT AND PREVENTION OF INFECTIOUS DIARRHEA AND ENTERIC INFECTION

THERAPEUTIC OPTION	INDICATIONS	AGENTS
1. Rehydration		
A. Oral rehydration therapy	Moderate to severe diarrhea	Oral rehydration solution sachets of preformulated salts and sugars are available commercially (see rehydrate.org). Basic home formulation = ½ teaspoon of salt, 6 level teaspoons of sugar, and 1 liter of clean water. For children in low-income regions, additional zinc sulfate (10 mg/day [children 6 mo]) decreases severity, duration, and recurrence.
B. Intravenous hydration	Severe diarrhea and volume depletion	Ringer lactate or normal saline + oral rehydration solution as tolerated
2. Symptomatic therapies	Mild to moderate watery diarrhea	Loperamide 4 mg × 1, then 2 mg after each unformed stool up to 16 mg (use cautiously; avoid with bloody/mucoid stool or fever) Bismuth subsalicylate 524 mg every 30-60 min as needed, up to eight doses per day
3. Empiric antibiotic therapy	Acute diarrhea	Azithromycin 1-g single dose PO or 500 mg qd × 3 Ciprofloxacin 500 mg PO q12h × 3 days or levofloxacin 500 mg PO q24h × 3
	Traveler's diarrhea	Rifaximin 200 mg PO tid × 3 days (noninvasive disease) Azithromycin 1000 mg PO × 1 Ciprofloxacin 500 mg PO q12h × 3 days or levofloxacin 500 mg PO q24h × 3 (resistance in many areas)

PO = orally; qd = once daily; tid = 3 times daily.

TREATMENT

Treatment must be based on the severity of the clinical disease as well as the patient's underlying conditions.[10] Even for patients who contact a physician, the majority of acute bacterial diarrheal infections will resolve spontaneously without specific antibiotics. Based on the patient's volume status, judicious oral fluid replacement will often suffice. For young infants with moderate-severe diarrheal illness in resource-limited regions and for the frail elderly, oral rehydration solutions (see Table 262-5) are recommended. However, some pathogens, particularly *Vibrio cholerae* (Chapter 278) and enterotoxigenic *E. coli* (Chapter 280), can cause massive diarrhea and rapid volume depletion that require intravenous hydration.

For patients without fever or bloody stools, antimotility drugs such as loperamide initially (adult dose: 4 mg then 2 mg after each unformed stool up to 16 mg/day) can offer symptomatic relief. However, loperamide may prolong or exacerbate the disease, especially in the absence of specific antibiotic treatment. Bismuth subsalicylate (524 mg either in liquid or pill form as needed every 30-60 minutes, not to exceed 4200 mg/day) can reduce symptoms in mild cases of diarrhea and viral gastroenteritis.[A1] Antimotility drugs as well as antibiotics should be avoided in cases of suspected or proven Shiga toxin–producing *E. coli* because of the enhanced risk of hemolytic uremic syndrome.

Probiotics are not useful as treatment.[A2] Given the predominance of viral causes and the self-limited nature of most bacterial infections, antibiotics typically can be reserved for patients who have underlying health conditions or for cases of moderate to severe diarrhea with fever, bloody or mucosal stools, six or more stools in a 24-hour period, or dehydration.[11] Whenever possible, treatment based on the identified organism and its sensitivity is preferred over a purely empiric approach.[12]

PREVENTION

The major strategy to prevent enteric infections is judicious avoidance of potentially contaminated food and drink, careful attention to expiration labels on foods and beverages, and elimination of fecal-oral transmission. For travelers to developing countries (Chapter 265), the admonition that "if you can't boil it, peel it, or heat it, don't eat it" remains sound advice for those venturing to endemic areas where the risk of diarrheal illness is high. Genomic sequencing can identify strains linked to outbreaks, pinpoint the source, and mitigate future risk.[13]

At present, safe and effective vaccines are available for only a limited number of enteric pathogens (see Table 265-2). The oral, live-attenuated vaccine for *V. cholerae* serogroup O1 (Chapter 278) is available for travelers to endemic areas with active cholera transmission, but this vaccine is not recommended for routine travel. A live oral and a parenteral vaccine are available for prevention of typhoid fever (Chapter 284), but neither will prevent all cases. Rotavirus vaccination (Chapter 350), which is licensed for infants beginning at 2 months of age, is more than 90% effective for preventing severe diarrhea.

Passive immunoprophylaxis in the form of encapsulated bovine colostrum antibodies raised against enterotoxigenic *E. coli* is available in the United States as a dietary supplement and may provide partial protection against traveler's diarrhea, but it does not target other pathogens. Antibiotic chemoprophylaxis for traveler's diarrhea (e.g., rifaximin 200 mg twice daily for trips of 2 weeks or less; Chapter 265) is best reserved for patients whose underlying conditions place them at very high risk, such as patients with advanced HIV. Bismuth subsalicylate can be used to prevent traveler's diarrhea, but it requires multiple daily doses and can cause salicylate intoxication, particularly in young children.

TABLE 262-6 NONINFECTIOUS CAUSES OF DIARRHEA

Running	Small bowel bacterial overgrowth
Fecal impaction	Systemic mastocytosis and eosinophilic gastroenteritis
Drugs and laxatives	Tropical sprue
Enteral feeding	Celiac sprue
Irradiation	Dermatitis herpetiformis
Pancreatic insufficiency	Intestinal graft-versus-host disease
Intestinal lymphangiectasia	Thyrotoxicosis
Foods (especially dietetic)	Adrenal insufficiency
Cirrhosis and biliary obstruction	Factitious
Diabetic diarrhea	Inflammatory bowel disease
Alcoholism	Food allergy
Collagenous colitis	Carcinoid
Microscopic colitis	Villous adenoma
VIPoma	Stress with autonomic stimulation
Ischemic bowel disease	
Irritable bowel syndrome	

From Dupont HL, Okhuysen PC. Approach to the patient with suspected enteric infection. In: Goldman L, Schafer AI, eds. *Goldman-Cecil Medicine*. Philadelphia: Elsevier; 2020:1832-1835.

PROGNOSIS

The overwhelming majority of acute infectious diarrhea resolves spontaneously or with short-term treatment. When travelers to low-income countries have persistent symptoms, repeat testing is indicated, especially to exclude persistent parasitic infections (e.g., *Giardia* [Chapter 322], *Cyptosporidium* [Chapter 321]) and bacterial infections (e.g., enteroaggregative *E. coli* [Chapter 280]). For nontravelers, persistent diarrhea should raise the possibility of noninfectious causes (Table 262-6 and Chapter 126), including the onset of inflammatory bowel disease (Chapter 127), gluten-sensitive enteropathy (Chapter 126), or irritable bowel syndrome (Chapter 123).

263 APPROACH TO THE PATIENT WITH URINARY TRACT INFECTION

DIMITRI DREKONJA

DEFINITIONS

Urinary tract infection (UTI) is bacterial or fungal infection of urine with associated signs or symptoms. The clinical presentation varies from cystitis (bladder or lower tract infection) to pyelonephritis (renal or upper tract infection) and urosepsis (systemic inflammatory response syndrome or septic shock from a urinary source). Asymptomatic bacteriuria is best considered a state of colonization that requires treatment in only specific clinical circumstances. Urethritis caused by *Chlamydia trachomatis*, *Ureaplasma urealyticum* (Chapter 264), or *Neisseria gonorrhoeae* (Chapter 275), as well as prostatitis (Chapter 114) and renal tuberculosis (Chapter 299), are addressed elsewhere in this text.

UTIs should be classified by the site of infection, tendency to recur, and presence or absence of complicating factors. Uncomplicated UTI occurs mainly in women with normal genitourinary tracts. Most uncomplicated UTIs present as cystitis; acute nonobstructive pyelonephritis also occurs in these women but at a lower frequency. Complicated UTI, which is often associated with host factors that facilitate the establishment and persistence of bacteriuria or infection (Table 263-1), typically refers to UTI occurring in patients with functional or structural abnormalities of the urinary tract. Uncomplicated UTI rarely occurs in young men, and any man who presents with a UTI should be assumed to have complicated infection until proven otherwise. Recurrent UTI is typically considered a reinfection when it is caused by a new bacterial strain and a relapse when the same strain that caused preceding infections is isolated, especially when the subsequent infection occurs within 30 days of completing therapy.

EPIDEMIOLOGY

UTI is the most common bacterial infection. It is somewhat more common in boys than in girls in the newborn period because of the higher frequency of urethral malformations in boys. Later in childhood, UTIs are more common in girls, as is asymptomatic bacteriuria. More than half of all healthy women experience at least one symptomatic UTI in their lifetime, and each year, 2 to 10% of women experience at least one episode. The estimated annual rates of outpatient clinical UTI are 5.4/100 person-years based on antibiotic prescriptions and 2.6/100 person-years based on a positive urine culture.[1]

UTI is uncommon in men with a normal genitourinary tract but increases after the age of 65 years, primarily attributable to prostatic hypertrophy and prostatitis (Chapter 114). The frequency of infection in patients with complicating factors varies by the abnormality that promotes infection. For example, patients who have a neurogenic bladder have continuing high rates of infection, but patients whose abnormalities can be corrected will no longer be at an increased risk of infection after the issue is corrected. UTI is also one of the most common hospital-acquired infections; about 80% of these are a consequence of the use of an indwelling bladder catheter. However, many of these "catheter-associated" UTIs are actually asymptomatic bacteriuria detected via unnecessary urine cultures.

Asymptomatic bacteriuria is common. Its prevalence increases from 1 to 2% of schoolgirls to 3 to 5% of sexually active premenopausal women, 10 to 20% of healthy postmenopausal women, and 40 to 50% of elderly women in nursing homes. UTIs are infrequent in men until older ages, with 5 to 10% of elderly men in the community and 35 to 40% of men in nursing homes having bacteriuria. Patients with genitourinary complications also have a very high prevalence of bacteriuria. For example, 50% of patients with a neurogenic bladder and without an indwelling catheter and virtually 100% of patients with chronic indwelling catheters have bacteriuria.

TABLE 263-1 HOST FACTORS ASSOCIATED WITH COMPLICATED URINARY TRACT INFECTION

	EXAMPLES
Obstruction	Urethral or ureteric strictures Tumor Diverticula Pelvicalyceal junction obstruction Prostate enlargement Urolithiasis Extrinsic compression
Functional	Neurogenic bladder Vesicoureteral reflux Anatomic defects Pregnancy Turbulent urethral urine flow Cystocele
Urologic interventions	Urethral or suprapubic catheters Urologic surgery Ureteric stents Nephrostomy tubes Cystoscopy Neobladders
Metabolic or congenital diseases	Urethral valves Polycystic kidneys Nephrocalcinosis Medullary sponge kidney
Immunologic abnormalities	Renal transplantation

PATHOBIOLOGY

Acute uncomplicated UTI follows ascension of normal gut flora, which have colonized the vagina and periurethral mucosa, into the bladder or kidney. The ability of these uropathogenic organisms, usually *Escherichia coli*, to colonize and to persist within the urinary tract is dependent on an array of virulence factors that include adhesins, toxins, and iron-scavenging proteins. Uromodulin, which is the most abundant protein in human urine, forms filaments that antagonize the adhesion of uropathogens and allows their clearance by micturition.[2] The organism's virulence is a major determinant of whether symptomatic infection develops and whether it is manifested as cystitis or pyelonephritis. Bacterial strains that cause uncomplicated infection typically express the FimH adhesin, but this adhesin is not specific for UTI. *E. coli* isolated from uncomplicated pyelonephritis are characterized by the presence of the P fimbria adhesin Gal(α1-4) Galβ disaccharide globoside, which initiates mucosal inflammation. Adherence of organisms in the bladder or kidney activates the innate immune response, thereby leading to release of cytokines, particularly interleukin-6 and interleukin-8, and mobilizes leukocytes. This process results in pyuria as well as local or systemic symptoms, including fever in patients with pyelonephritis.

The occurrence of acute uncomplicated UTI in healthy premenopausal women is determined by both genetic and behavioral factors. A genetic predisposition is supported by observations that a history of prior UTI is consistently one of the strongest associations with recurrent uncomplicated UTI, and women who experience these infections report a higher proportion of first-degree female relatives with recurrent UTI than do those without infection. One established genetic association is being a nonsecretor of the ABH blood group antigen (being unable to secrete blood type antigens into body fluids), with more avid binding of uropathogenic organisms to the vaginal epithelium in nonsecretors. Genetic polymorphisms affecting innate immunity are correlated with increased frequency of infection as well as with specific presentations.

Behavioral risk factors are similar for women for cystitis, pyelonephritis, and asymptomatic bacteriuria. The strongest behavioral factors are sexual intercourse and spermicide use. For sexually active premenopausal women, 75 to 90% of episodes are attributed to intercourse. This association is primarily attributed to ascension of periurethral organisms into the bladder during intercourse, but unprotected vaginal sex may also reduce endogenous anti–*E. coli* activity. The normal lactobacillus flora of the vagina maintains an acid environment that prevents colonization by potential uropathogens, and spermicides suppress this normal flora. Despite popular perceptions, use of oral contraceptives or condoms, postcoital voiding, type of underwear, personal hygiene after voiding or defecating, and taking a bath rather than a shower are not associated with recurrent UTI. Sexual intercourse is not a major contributor to UTI in postmenopausal women, in whom the most important determinants of infection are a history of UTI at a younger age and nonsecretory status (see earlier).

The risk of complicated UTI is determined by the underlying abnormality. Genitourinary abnormalities facilitate infection by increasing the entry of organisms into the bladder, such as via intermittent catheterization or urologic procedures, and the persistence of organisms within the urinary tract because

ABSTRACT

Urinary tract infection (UTI) is the most common bacterial infection, ranging in severity from cystitis to urosepsis. In younger populations UTI is more common in women, but after the age of 65 the difference between sexes narrows. The microbiology of UTI is dominated by gram-negative organisms, although staphylococci, enterococci, and *Candida* species are important exceptions. Urine testing will reveal pyuria and bacteriuria in nearly all patients with UTI; however, both pyuria and bacteriuria can be present in asymptomatic patients, and only symptoms can differentiate UTI from asymptomatic bacteriuria. Other than during pregnancy and prior to urologic procedures, treatment of asymptomatic bacteriuria is not recommended. Treatment of UTI depends on the specific syndrome. Cystitis can be treated with short courses of antimicrobials, including some that achieve high concentrations only in the bladder. More severe infections, such as pyelonephritis and urosepsis, require slightly longer durations of treatment with agents that reach the renal parenchyma and achieve therapeutic levels in the blood. Increasing antimicrobial resistance among gram-negative organisms has made the treatment of UTI more challenging, as has the use of indwelling urinary catheters.

of incomplete voiding or their persistence in biofilms on urologic devices. The determinants that promote symptomatic infection rather than asymptomatic colonization are not well characterized. However, obstruction and mucosal trauma with bleeding are well-recognized antecedents for bacteremia and sepsis in patients with preexisting bacteriuria. Although it is generally accepted that patients with diabetes have an increased incidence of UTI, this risk correlates more with long-term complications of diabetes, such as neurogenic bladder, than with the diabetes itself. Patients with poorly controlled diabetes, however, are at risk for more severe manifestations of infection.[3]

Acquisition of bacteriuria in individuals with indwelling urinary devices, including catheters, stents, and nephrostomy tubes, is primarily attributable to the development of biofilms along the device. Biofilms are composed of an extracellular polysaccharide material that is produced by the organisms and that incorporates urine components, including Tamm-Horsfall protein, as well as magnesium or calcium ions. After insertion of the device, a conditioning layer composed of proteins and other host components immediately coats the device. Organisms adhere to this conditioning layer and initiate the formation of biofilm. Colonization usually begins at the urethral orifice or in the drainage bag, and the biofilm then ascends the catheter. Organisms growing in the biofilm persist in an environment relatively protected from antibiotics or host defenses. For patients who have an indwelling catheter, the acquisition of bacteriuria occurs at a rate of 3 to 7% per day. Bacteriuria that follows insertion of an indwelling catheter initially is usually with a single organism, but polymicrobial flora, particularly including *Proteus mirabilis*, is typical in mature biofilms on chronic indwelling devices. *P. mirabilis* strains may produce copious biofilm, and the related production of urease creates an alkaline environment, thereby leading to precipitation of calcium and magnesium ions. The resultant "crystalline biofilm," which is similar to what causes infection-related kidney stones, may obstruct an indwelling catheter. About 80% of episodes of obstructed urinary catheters are attributable to *P. mirabilis*.

Etiology

In all types of UTI, *E. coli* (Chapter 280) is the dominant bacterial species, and it causes up to 85% of all symptomatic UTIs in women with community-acquired infections (Table 263-2).[4] The second most common species causing uncomplicated cystitis is *Staphylococcus saprophyticus*, which is isolated more frequently in later summer and early fall. In patients who have recurrent complicated UTIs, species such as *Enterococcus faecalis* (Chapter 270), *Enterococcus faecium*, *Klebsiella* species (Chapter 281), *Proteus* species (Chapter 281), *Providencia stuartii*, and *Morganella morganii* become more common. In patients with very frequent recurrences or with bladder catheters, particularly patients in hospitals and nursing homes where antimicrobials are frequently used, *E. coli* accounts for less than 50% of UTIs, and patients instead may have infections caused by *Pseudomonas aeruginosa* (Chapter 282), *Acinetobacter baumannii*, *Serratia marcescens*, and *Stenotrophomonas maltophilia* isolated. Urolithiasis attributed to infected stones is associated with urease-producing organisms; the alkaline urine created facilitates struvite formation.[5] Repeated antimicrobial treatment administered to patients with recurrent complicated UTI often leads to increased antimicrobial resistance in the organisms isolated from recurrent infections. In health care facilities, the catheterized urinary tract is the most common site for the isolation of multiple drug–resistant gram-negative organisms, including extended-spectrum β-lactamase–producing and carbapenemase-producing Enterobacteriaceae. *Candida* sp is the most common cause of fungal UTI. Patients with *Candida* UTI often have diabetes or an indwelling urinary catheter, as well as prior exposure to broad-spectrum antimicrobial agents.

TABLE 263-2 MICROBIAL ETIOLOGY OF URINARY TRACT INFECTIONS

ORGANISMS	CLINICAL CHARACTERISTICS
GRAM-NEGATIVE BACTERIA	
Escherichia coli	Typical
Klebsiella pneumoniae	Often reinfection
Enterobacter spp	Often reinfection or health care–associated infection*
Proteus spp	May indicate calculi; frequent with devices
Providencia stuartii	Often reinfection or health care–associated infection*
Morganella morganii	Often reinfection or health care–associated infection*
Serratia marcescens	Often health care–associated infection*
Acinetobacter baumannii	Often health care–associated infection*
Burkholderia spp	Often health care–associated infection*
Pseudomonas aeruginosa	Often health care–associated infection*
Stenotrophomonas maltophilia	Often health care–associated infection*
GRAM-POSITIVE BACTERIA	
Staphylococcus saprophyticus	Most common during late summer and fall
Staphylococcus aureus	May indicate focus outside the genitourinary tract
Enterococcus spp	Often reinfection
Other gram-positive bacteria	In most cases contaminants or colonizers
FUNGI	
Candida spp	May indicate focus outside the genitourinary tract

*Includes hospital and nursing home care.

TABLE 263-3 CLINICAL SYMPTOMS OF URINARY TRACT INFECTIONS

TYPE OF URINARY TRACT INFECTION	TYPICAL SIGNS OR SYMPTOMS
Cystitis	Frequency Dysuria Urgency Stranguria (difficulty in micturition) Suprapubic pain Hematuria
Pyelonephritis	Costovertebral angle pain or tenderness Fever Chills Cystitis symptoms (may be absent)
Urosepsis	Fever Chills, rigors Sepsis syndrome

CLINICAL MANIFESTATIONS

The onset of cystitis is rapid, and symptoms (Table 263-3) usually develop within 24 hours. Clinically, the lack of vaginal discharge can differentiate cystitis from urethritis (Chapter 264) caused by chlamydia, ureaplasma, or gonococci. Women who experience recurrent episodes of acute uncomplicated UTI are more than 90% reliable for self-diagnosis.

Pyelonephritis may also have a rapid onset and may or may not be associated with symptoms of cystitis. Bacteremia occurs in 10 to 30% of patients but does not have prognostic significance. The typical flank pain and tenderness, which result from inflammation and edema of the renal parenchyma, may be masked by the intake of analgesic drugs such as acetaminophen, which may also reduce the fever. An important differential diagnosis is renal calculus (Chapter 111), in which the pain may have a similar location but fever is not present unless the stone is complicated by infection.

Complicated UTI manifests across a clinical spectrum from minimal voiding abnormalities to symptoms consistent with cystitis, pyelonephritis, or severe sepsis. Urosepsis is a life-threatening condition, usually associated with bacteremia. Obstruction, which is more common in men with prostatic hypertrophy (Chapter 114), or trauma to the mucosa from an indwelling catheter or urologic surgery may precipitate bacteremia. Patients who present with urosepsis typically have complicated UTI rather than nonobstructive pyelonephritis. Urosepsis can present with or progress to septic shock (Chapter 94), which requires life-supporting treatment in addition to antibiotics.

DIAGNOSIS

Laboratory Findings

The hallmark of the diagnosis of UTI is demonstration of bacteriuria in a urine sample. A pretherapy urine culture specimen should be obtained for all patients who present with pyelonephritis, urosepsis, or complicated UTI or when the diagnosis is uncertain. Routine culture is not generally recommended for acute uncomplicated cystitis because the clinical presentation is characteristic, and empiric short-course therapy often resolves

symptoms by the time the culture is available. However, frequently recurrent cystitis raises the likelihood of bacterial resistance, so a culture should be obtained in this situation, in patients with an early recurrence post-therapy, and in patients with persistent symptoms despite appropriate empiric antimicrobial therapy.

Urine specimens for culture must be collected before institution of antimicrobial therapy because the urine is rapidly sterilized after initiation of systemic antimicrobials. The usual collection method is a midstream urine sample to limit contamination. For patients with indwelling catheters, specimens should be collected from the catheter port and not from the drainage bag. All specimens should be taken promptly to the laboratory to prevent growth of contaminants during transportation.

The interpretation of the quantitative urine culture varies with the clinical presentation and collection method (Table 263-4). Significant bacteriuria is usually 10^5 CFU/mL or more, where one colony-forming unit (CFU) is one or more bacterial cells forming a colony when growing on an agar plate. In women with symptoms of uncomplicated cystitis, 10^2 CFU/mL or more in midstream urine of *E. coli* or *S. saprophyticus* is consistent with infection. Other gram-positive organisms at any quantitative count should be interpreted as contaminants, except for *Staphylococcus aureus*, which may be identified in the urine owing to renal filtration in patients who have *S. aureus* bacteremia or endocarditis.

Pyuria is present in most patients with symptomatic UTI or asymptomatic bacteriuria. Many other abnormalities are, however, associated with pyuria, and the presence of pyuria does not diagnose infection or differentiate symptomatic from asymptomatic infection. The absence of pyuria has a high negative predictive value to exclude UTI for most patients. However, the absence of pyuria in a urine specimen from a woman with symptoms compatible with cystitis is not an indication to withhold empiric antimicrobial therapy.

For rapid screening for possible bacteriuria, identification of nitrite by dipstick urine testing may be useful, with a sensitivity of about 90%.[6] Gram-negative bacteria, with the exception of *P. aeruginosa*, will metabolize nitrate to nitrite, which can be demonstrated by a color reaction on a dipstick. Gram-positive bacteria and fungi do not metabolize nitrate. The technique is rapid (<1 minute) and inexpensive. It has a high degree of specificity but is insensitive because it does not detect infections caused by gram-positive organisms.

Conversely, some patients with evident pyuria will have negative urine cultures. Infectious causes of sterile pyuria include tuberculosis (Chapter 299), gonorrhea (Chapter 275), chlamydia (Chapter 294), mycoplasma (Chapter 293) and ureaplasma (Chapters 293 and 264), genital herpes (Chapter 345), trichomoniasis (Chapter 324), fungal infections (Chapter 314), and schistosomiasis (Chapter 326).

Blood culture specimens should be obtained in all patients with suspected urosepsis. Patients with acute pyelonephritis, but not those with acute cystitis, have increased serum levels of C-reactive protein.

Imaging

Early imaging should be performed in any patient with urosepsis to identify abnormalities that require immediate source control. The optimal imaging modality is a computed tomography scan with intravenous contrast. Magnetic resonance imaging may not identify gas in tissues or small stones. Ultrasound may provide a rapid examination to exclude significant obstruction.

TABLE 263-4 INTERPRETATION OF THE QUANTITATIVE URINE CULTURE

	QUANTITATIVE BACTERIAL COUNT
Asymptomatic bacteriuria	$\geq 10^5$ CFU/mL in two consecutive specimens for women
Acute uncomplicated cystitis	$\geq 10^2$ CFU/mL of *Escherichia coli* or *Staphylococcus saprophyticus*
Acute uncomplicated pyelonephritis	$\geq 10^4$ CFU/mL (95% have $\geq 10^5$ CFU/mL)
Complicated urinary tract infection	$\geq 10^5$ CFU/mL (lower counts may occur with diuresis)
Intermittent or in and out catheter collection	$\geq 10^2$ CFU/mL
Suprapubic or percutaneous aspiration	Any organisms isolated

CFU = colony-forming unit.

Investigations are also indicated for patients with delayed response or failure to respond to appropriate antimicrobial therapy or with early relapse of pyelonephritis after completion of therapy. Because the optimal management of a complicated urinary infection requires characterization and potential correction of any underlying anatomic abnormalities, selected patients may require imaging studies for the diagnosis of vesicoureteral reflux (Chapter 113) or to characterize differential renal function.

Differential Diagnosis

Clinical manifestations will usually differentiate acute cystitis and acute pyelonephritis (Table 263-5). New-onset frequency, dysuria, and urgency without accompanying vaginal discharge or pain have a positive predictive value of 90% for acute cystitis. The differential diagnosis for women presenting with acute irritative lower tract symptoms includes sexually transmitted infections, vulvovaginal candidiasis, and noninfectious causes such as interstitial cystitis. Some patients who present with only lower tract symptoms may have renal infection, referred to as occult pyelonephritis. Patients with appendicitis (Chapter 128) and cholecystitis (Chapter 141) can present with flank pain similar to right-sided pyelonephritis, and pelvic inflammatory disease (Chapter 264) may be misdiagnosed as urinary infection.

TREATMENT

Treatment depends on the extent of the infection (e.g., cystitis versus pyelonephritis), the presence or absence of underlying anatomic issues, and concerns about urosepsis (Fig. 263-1). Symptomatic UTIs should be treated with antimicrobials to decrease the duration of symptoms and prevent the progression of the infection. For pyelonephritis, another goal is to limit damage to renal tissue. For urosepsis, antimicrobials selected should be excreted renally, so high antimicrobial concentrations are achieved in the renal parenchyma and urine.

Cystitis

Patients with uncomplicated recurrent cystitis usually can be effectively managed with a strategy of empiric early self-treatment (Table 263-6), which usually leads to prompt improvement of symptoms. In other patients or patients who have frequent recurrences, the initial empiric treatment should be modified, as needed, based on the results of culture and sensitivity testing.[7]

In either situation, the shortest effective duration should be prescribed. Trimethoprim, trimethoprim-sulfamethoxazole, fosfomycin, pivmecillinam, and nitrofurantoin are recommended first-line treatments because they are effective with relatively short courses,[8] and their limited effect on normal flora reduces the risk of developing antimicrobial resistance. For an uncomplicated UTI in women, nitrofurantoin (100 mg three times daily for 5 days) is associated with the fewest adverse effects[9] and results in a significantly higher likelihood of clinical and microbiologic resolution at 28 days after completion of therapy compared with a single 3-gram dose of fosfomycin.[A1] Trimethoprim or trimethoprim-sulfamethoxazole should be selected for initial empiric therapy only if the local prevalence of resistance to these agents in community-acquired *E. coli* infections is less than 20%. Fluoroquinolones are not recommended for first-line therapy because of concerns about toxicity and the promotion of resistance. β-Lactam antimicrobials are about 10% less effective than the first-line agents. Nitrofurantoin and oral cephalosporins are preferred therapy for pregnant women because these are safe for the fetus.

For acute symptomatic relief, phenazopyridine (100 mg, 1 to 2 tablets up to three times daily after meals for up to 2 days) is effective. However, it should only be used in conjunction with antibiotics and not with antipyretics, since it can mask the symptoms of the infection. It can stain soft contact lenses and should not be used in patients who are wearing them.

Pyelonephritis

For antimicrobial treatment of pyelonephritis (Table 263-7), the initial decision is whether oral treatment alone will suffice or whether parenteral treatment is needed. Initial empiric intravenous therapy with an aminoglycoside (e.g., gentamicin) is associated with better outcomes and should be considered in areas with high rates of resistance to other antimicrobials.[10] After initial treatment with a parenteral drug, transition to oral treatment that achieves adequate tissue levels (i.e., trimethoprim-sulfamethoxazole, cefixime, or ciprofloxacin but not nitrofurantoin or fosfomycin) is normally possible at 24 to 48 hours if the patient has clinically improved. The recommended treatment time is 7 to 14 days, but 5 to 7 days is adequate for ciprofloxacin or levofloxacin.[A2,A3]

Complicated Urinary Infection

The antimicrobial regimen selected for treatment of complicated UTI should be individualized based on the site of infection, severity of the manifestations, new or presumed infecting organism and susceptibility, tolerance of the patient, and nature of the underlying abnormalities.[11,12] Oral or parenteral therapy is selected on the basis of the presentation and the likelihood of resistant organisms. When

symptoms are mild and not bothersome, it is reasonable to delay the initiation of antimicrobial therapy until results of the urine culture are available to allow optimal selection.

When bothersome or severe symptoms are present, empiric antimicrobial therapy should be initiated promptly. Previous urine culture results from the patient and recent history of antimicrobial exposure are helpful to assess the likelihood of resistant organisms. Options for complicated UTI with severe symptoms include intravenous plazomicin (15 mg/kg once daily) or meropenem (1 g every 8 hours) for 4 to 5 days, followed by sensitivity-guided oral therapy for another 5 to 6 days.[A4] Piperacillin-tazobactam (4.5 g every 8 hours for 7 days) and fosfomycin (6 g every 8 hours for 7 days) are about equally effective.[A5] Other options include meropenem-vaborbactam (2 g/2 g over 3 hours) or piperacillin-tazobactam (4.5 g over 30 minutes) every 8 hours for 4 to 5 days, followed by 5 to 6 days of oral sensitivity-guided therapy.[A6] Plazomicin and meropenem-vaborbactam are particularly useful for highly resistant organisms when treatment options are limited. Nitrofurantoin, either as initial treatment or as continuation after initial intravenous therapy, may be used for episodes of complicated bladder infection but is not effective for renal infection and is contraindicated in individuals with renal failure. Fosfomycin (with dosing adjustments for patients with impaired renal function) can also be used for complicated bladder but not renal infection. The empiric therapy selected should be reassessed after 48 to 72 hours, by which time the urine culture result should be available, so the response to initial therapy can be modified to an agent to which the organism is susceptible, irrespective of the clinical response. Antibiotic prophylaxis to reduce the risk of subsequent symptomatic infection at the time of catheter removal remains controversial.

Asymptomatic Bacteriuria

Evidence supports treatment of asymptomatic bacteriuria before urologic procedures with anticipated trauma to the genitourinary mucosa. There is also evidence supporting treatment of asymptomatic bacteriuria in pregnant women (see Pregnancy).[A7] Otherwise, asymptomatic bacteriuria is increasingly recognized as a major driver of unnecessary use of antimicrobial agents.[I1] For all other populations, including elderly women and men, treatment of asymptomatic bacteriuria has not been associated with improved outcomes but is consistently followed by reinfection with organisms of increasing antimicrobial resistance.

TABLE 263-5 DECISION PROCESS FOR DIAGNOSIS AND TREATMENT OF UPPER (PYELONEPHRITIS) VERSUS LOWER (CYSTITIS) URINARY TRACT INFECTIONS

	CYSTITIS	PYELONEPHRITIS
SIGNS AND SYMPTOMS		
Fever	No	Yes
Dysuria	Yes	May be present
Frequency	Yes	May be present
Flank pain	No	Yes
DIAGNOSIS		
Pyuria	Yes	Yes
Nitrite test result	Normally positive	Normally positive
Bacteriuria	Yes	Yes
C-reactive protein	Normal	Increased
Blood cultures	Negative	Positive in ≈10-30%
TREATMENT		
First line	Short-term oral therapy (Table 263-6)	Oral: fluoroquinolone for 7 days; parenteral: cephalosporin, fluoroquinolone, or aminoglycoside for 7-14 days (Table 263-7)
Second line	Fluoroquinolone for 3 days or cephalosporin for 7 days	Injectable cephalosporin until afebrile, followed by oral step-down for total of 2 weeks
Pregnant women	Nitrofurantoin or cephalosporin for 5-7 days	Injectable cephalosporin until afebrile, followed by oral cephalosporin for 14 days

TABLE 263-6 ANTIMICROBIALS USED TO TREAT CYSTITIS

ANTIMICROBIAL	DOSE* AND DURATION
FIRST-LINE THERAPY	
Trimethoprim	100-150 mg q12h for 3 days
Trimethoprim-sulfamethoxazole	160/800 mg q12 for 3 days or 320/1600 mg single dose
Nitrofurantoin	50-100 mg q8h for 5-7 days
Nitrofurantoin macrocrystals	100 mg bid for 5 days
Fosfomycin trometamol	3-g single dose
Pivmecillinam	400 mg bid for 3-5 days
OTHER	
Amoxicillin-clavulanate	500 mg (amoxicillin dose) q8h for 7 days
Amoxicillin	500 mg tid for 7 days
Cefpodoxime proxetil	100 mg bid for 3 days
Cefuroxime axetil	500 mg bid for 7 days
Cefixime	400 mg/day for 7 days
Ceftibuten	400 mg/day for 5-7 days
Norfloxacin†	400 mg q12h for 7 days
Ciprofloxacin†	250 mg q12h for 3-7 days (500 mg qd extended release)
Levofloxacin†	250-500 mg/day for 3-7 days

*Doses given are for adults with normal renal function. The need to reduce dosages because of renal impairment related to infection in the kidneys, other renal diseases, or advanced age should always be considered.

†The FDA advises that the side effects of fluoroquinolones outweigh their benefits when patients with acute uncomplicated urinary tract infections have other options.

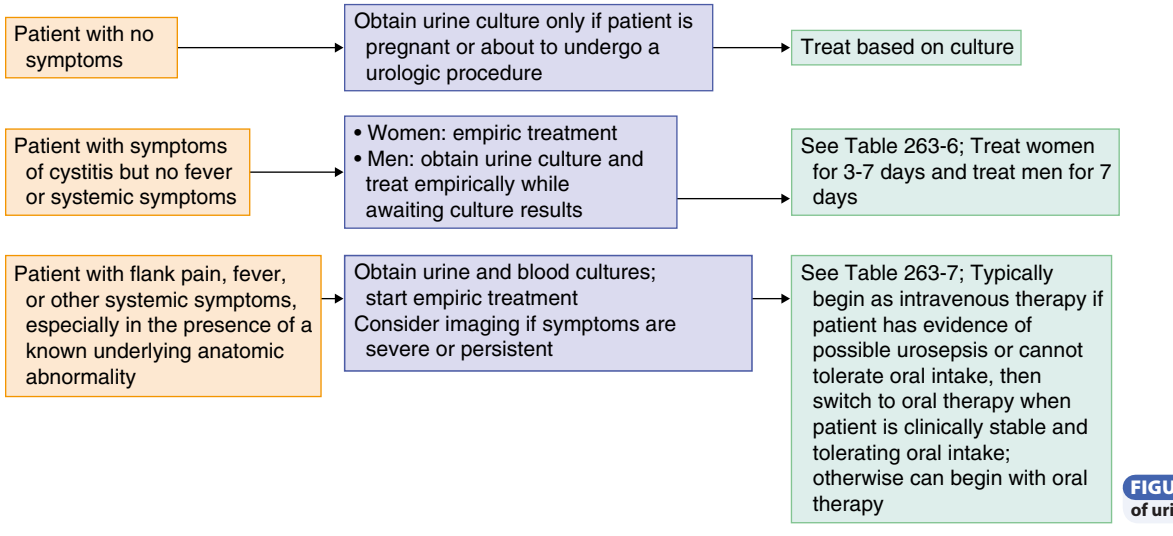

FIGURE 263-1. Approach for treatment of urinary tract infection.

TABLE 263-7 ANTIMICROBIALS USED TO TREAT PYELONEPHRITIS AND UROSEPSIS

ROUTE OF ADMINISTRATION AND ANTIMICROBIAL	DOSE*
PARENTERAL†	
First-Line Therapy	
Piperacillin-tazobactam	3.375 g q6h
Cefepime	2 g q8-12h
Cefotaxime	1 g q8h
Ceftriaxone	1-2 g qd
Ciprofloxacin	400 mg q12h
Levofloxacin	750 mg/day
Other	
Ceftazidime	1 g q8-12h
Ertapenem	1 g qd
Meropenem	500 mg q6h
Doripenem	500 mg q8h
Amikacin	15 mg/kg/day
Gentamicin	4.5 mg/kg/day
Tobramycin	4.5 mg/kg/day
Trimethoprim-sulfamethoxazole	160/800 mg q12h
ORAL	
First-Line Therapy	
Ciprofloxacin	500 mg q12h
Levofloxacin	250-500 mg/day
Other	
Amoxicillin-clavulanate	500 mg (amoxicillin dose) q8h
Cefuroxime axetil	500 mg q12h
Cefixime	400 mg/day
Ceftibuten	400 mg/day

*Doses given are for adults with normal renal function. The need to reduce dosages because of renal impairment should always be considered.

†Parenteral therapy should be converted to oral therapy once clinical stability has been achieved and susceptibility results have returned, which is typically 2-3 days after starting therapy. See text for details on duration of therapy.

In patients with indwelling catheters, bacteriuria should not be treated unless the patient has symptoms attributed to urinary infection. Administration of antimicrobials to catheterized patients with asymptomatic bacteriuria inevitably results in reinfection with more resistant organisms. The optimal treatment for patients with nonspecific symptoms (fatigue, lethargy, poor concentration) and bacteriuria is unknown. Supportive care with observation versus a trial of antimicrobial treatment are potentially valid but unstudied options.

Infections in Elderly Men

Urinary tract infection is the leading cause of bacteremia in older men, almost always in the context of underlying prostate, bladder, or kidney abnormalities, including bacterial prostatitis (Chapter 114). For lower urinary tract infections, initial empiric therapy is the same as for cystitis in women. However, culture-directed antimicrobial therapy is indicated as soon as possible, and antibiotics do not obviate the need for a urologic consultation and a full urologic evaluation, which then guides further therapy. The duration of treatment is typically longer than for women, with 14 days of trimethoprim-sulfamethoxazole or ciprofloxacin being no better than 7 days of the same agent in men without fever.[A8] In men with a febrile UTI, however, 14 days of therapy is slightly better than 7 days, mainly by somewhat reducing the likelihood of a recurrence.[A9] For men without a history of recurrence, the benefits of shorter therapy likely outweigh this small potential benefit.

Urinary Obstruction

Obstruction, whether from a urinary stone, an enlarged prostate, or a malfunctioning catheter, can lead to serious illness if urine is colonized with bacteria. In the setting of an obstructed urinary system, the combination of rising pressure from the obstruction and rapidly multiplying bacteria facilitates systemic infection (e.g., bacteremia and sepsis) unless the urinary system is drained. Drainage can be as simple as placing a temporary urinary catheter or replacing an obstructed catheter. If urologic intervention is unavailable or unable to achieve drainage, percutaneous drainage can be performed by an interventional radiologist. Regardless of the method, drainage should be achieved urgently, and antimicrobial agents for pyelonephritis or urosepsis should be initiated.

Urosepsis

The principles for managing urosepsis are similar to those for patients with severe sepsis from any site (Chapter 94). Parenteral empiric antimicrobial treatment (e.g., piperacillin/tazobactam 3.375 g IV q6h or ceftriaxone 1 to 2 g IV q24 hours) and supportive care should be initiated promptly,[13] but empiric treatment need not routinely include coverage for *Pseudomonas*.[14] The selected antimicrobials should provide broad-spectrum coverage for potential uropathogens, including resistant bacteria. Antimicrobial therapy should be reassessed when urine and blood culture results become available. Similar to pyelonephritis, therapy can be transitioned to the oral route when vital signs have normalized and oral intake is tolerated.

Perinephric Abscess

A perinephric abscess should be suspected in patients who have persistent fever and abdominal discomfort 48 to 72 hours after the initiation of active antimicrobial therapy. A contrast-enhanced CT scan is the preferred imaging modality, but nonenhanced CT, ultrasound, and MRI are alternatives in the setting of renal failure. If a perinephric abscess is identified, effective drainage is the mainstay of treatment. Most abscesses can be safely and effectively drained by an interventional radiologist, but loculated abscesses or abscesses that are difficult to access may require open surgical drainage.

Funguria

Funguria should be treated only when accompanied by symptoms of UTI.[15] Symptomatic infection is treated with fluconazole 400 mg once daily for 1 day, followed by 200 mg once daily for 7 to 14 days. If *Candida* sp resistant to fluconazole is isolated, liposomal amphotericin is the recommended alternative therapy because other antifungals have limited renal excretion. An infectious diseases expert should guide dosing, which can vary by product. The optimal duration of therapy is uncertain, but 7 to 10 days of amphotericin is usually suggested.

Follow-up

Patients do not require follow-up urine cultures unless symptomatic infection persists or recurs. If the patient develops an early (<30 days) recurrence, urine culture and sensitivity analysis is needed to ensure that appropriate antimicrobial therapy can be prescribed. If patients require empiric treatment while awaiting these results, a regimen should be selected based on the most recently available urine culture.

TABLE 263-8 PROPHYLACTIC REGIMENS TO PREVENT RECURRENT URINARY TRACT INFECTION IN WOMEN

PREFERRED	OTHER
Long-term low dose Nitrofurantoin 50 mg od or 100 mg daily Trimethoprim-sulfamethoxazole, 40/200 mg daily or every other day	Cephalexin 250-500 mg daily* Norfloxacin 200 mg daily Ciprofloxacin 125 mg daily
Postcoital (single dose) Nitrofurantoin 50 or 100 mg* Trimethoprim-sulfamethoxazole 40/200 mg Trimethoprim 100 mg	Cephalexin 250 mg* Ciprofloxacin 125 mg Norfloxacin 200 mg

*Suitable for use in pregnancy.

PREVENTION

Screening

Since asymptomatic bacteriuria should be treated only in selected circumstances (see earlier), routine screening for asymptomatic bacteriuria is not recommended.[16]

Recurrent Uncomplicated UTI

Premenopausal women with recurrent acute uncomplicated UTI should avoid the use of spermicides and may benefit from increasing their daily water intake to more than 1.5 L/day.[A10] Prophylactic D-mannose (420 mg to 2 g over the counter) can be considered, particularly if *E. coli* is the organism that is repeatedly isolated.[A11] For women with frequent recurrent acute uncomplicated UTI (more than two in 6 months or three in 12 months) presenting as cystitis or pyelonephritis, prophylactic antimicrobial therapy is effective, either as long-term low-dose prophylaxis[A12] or as postcoital prophylaxis (Table 263-8). The use of cranberry tablets or juice does not reliably decrease bacteriuria[A13]

or the frequency of recurrent infection, and probiotics are not effective. For postmenopausal women, topical vaginal estrogens can be tried to decrease the frequency of infection, but postcoital antibiotics are more effective for women with frequent recurrences.[17] Systemic estrogen therapy, however, is not associated with a decreased frequency of UTI, and it generally should be avoided in women with frequent recurrences.

Pregnancy

Current recommendations suggest pregnant women should be screened for asymptomatic bacteriuria early in the pregnancy, usually at 12 or 16 weeks.[18] If bacteriuria is present, these women should be treated and have subsequent follow-up culture specimens obtained monthly. If either asymptomatic colonization or recurrent infection occurs, prophylactic antimicrobial therapy with either cephalexin or nitrofurantoin should be considered through the duration of the pregnancy to decrease the risk of pyelonephritis in later pregnancy.[19]

Prior Complicated UTI

Prophylactic antimicrobial therapy has not been shown to be effective for patients with complicated UTI, including patients with spinal cord injury or with chronic indwelling catheters. In these patients, the abnormality leading to impaired voiding means that bacteriuria is unavoidable, and antimicrobial therapy will promote bacteriuria with increasingly resistant organisms. For patients with recurrent UTIs and a neurogenic bladder after spinal cord injury, however, limited data suggest that cyclic antibiotics (the alternate weekly use of two different antibiotics) may be efficacious without promoting antibiotic resistance.[A14]

Infection Control

Infection control programs of health care facilities (Chapter 261) should include practices to prevent catheter-associated UTI.[20] Evidence-based guidelines provide clear recommendations, including ongoing surveillance. The most important intervention is to avoid the use of an indwelling catheter wherever possible and, when there are clear indications for catheter use, to limit the duration to as short a time as possible. Meatal cleaning with chlorhexidine solution before catheter insertion can decrease the incidence of catheter-associated asymptomatic bacteriuria and UTIs.[A15] For adults who require intermittent self-catheterization, continuous antibiotic prophylaxis can reduce recurrent UTIs but at the risk of developing resistant organisms.[A16] The future development of biofilm-resistant materials may help reduce the problem of catheter-associated UTI.

PROGNOSIS

The prognosis of uncomplicated cystitis and pyelonephritis is good. Women with acute uncomplicated cystitis do not receive antimicrobial therapy, and symptoms will usually resolve by 1 to 2 weeks. Women with very frequent recurrent, acute uncomplicated UTI experience no long-term adverse outcomes, such as renal impairment or hypertension. A small proportion of women with severe presentations of acute nonobstructive pyelonephritis develop renal scars, but these are not associated with impaired renal function. Whether men also develop such scars is unknown. Patients with frequent recurrent complicated UTI may experience substantial morbidity with recurrent infections, but poor long-term medical outcomes are usually determined by the underlying abnormality rather than by infection. A perinephric abscess generally is cured by appropriate therapy and is not associated with long-term sequelae. Patients with urosepsis have a fatality rate of about 10%. Factors increasing the risk of death are advanced age and significant underlying diseases, as well as inadequate initial antimicrobial treatment.

264 APPROACH TO THE PATIENT WITH A SEXUALLY TRANSMITTED INFECTION

HEIDI SWYGARD AND MYRON S. COHEN

SEXUALLY TRANSMITTED INFECTIONS

DEFINITION

Sexually transmitted infections (STIs) include a wide variety of organisms that are transmitted through intimate contact involving skin or mucosal surfaces of the oropharynx, vagina, penis, and rectum.[1] STIs can generally be divided into five broad categories (syndromes): urethritis, genital ulcers, epithelial cell disorders, vaginal discharge, and ectoparasites (Table 264-1). Gender inclusive models (Chapter 215) and programs of care are recommended for all persons who would benefit from such services.

EPIDEMIOLOGY

The interaction between the host and the sexually transmitted pathogen plays a critical role, and characteristic tissue changes offer clues about etiology. Several sexually transmitted pathogens cause local inflammation only (*Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*), with the potential for local tissue invasion (*N. gonorrhoeae*, *C. trachomatis*) or systemic dissemination (*N. gonorrhoeae*). Some sexually transmitted pathogens cause tissue ulceration (*Treponema pallidum*, *Haemophilus ducreyi*, herpes simplex viruses 1 and 2, *Klebsiella granulomatis*). Human papillomaviruses cause epithelial cell changes and predispose to neoplasm. Several sexually transmitted pathogens (human immunodeficiency virus [HIV], hepatitis B and C viruses, cytomegalovirus) routinely enter through the genital tract without causing any local changes.

Other important systemic diseases that can be acquired through sexual transmission include Zika virus, Ebola virus, Lassa fever, and monkeypox (Chapters 343, 351, and 352). Although these infections can present with genital cutaneous lesions that can be confused with herpes simplex virus, they can cause systemic signs and symptoms that can be fatal.

or the frequency of recurrent infection, and probiotics are not effective. For postmenopausal women, topical vaginal estrogens can be tried to decrease the frequency of infection, but postcoital antibiotics are more effective for women with frequent recurrences.[17] Systemic estrogen therapy, however, is not associated with a decreased frequency of UTI, and it generally should be avoided in women with frequent recurrences.

Pregnancy

Current recommendations suggest pregnant women should be screened for asymptomatic bacteriuria early in the pregnancy, usually at 12 or 16 weeks.[18] If bacteriuria is present, these women should be treated and have subsequent follow-up culture specimens obtained monthly. If either asymptomatic colonization or recurrent infection occurs, prophylactic antimicrobial therapy with either cephalexin or nitrofurantoin should be considered through the duration of the pregnancy to decrease the risk of pyelonephritis in later pregnancy.[19]

Prior Complicated UTI

Prophylactic antimicrobial therapy has not been shown to be effective for patients with complicated UTI, including patients with spinal cord injury or with chronic indwelling catheters. In these patients, the abnormality leading to impaired voiding means that bacteriuria is unavoidable, and antimicrobial therapy will promote bacteriuria with increasingly resistant organisms. For patients with recurrent UTIs and a neurogenic bladder after spinal cord injury, however, limited data suggest that cyclic antibiotics (the alternate weekly use of two different antibiotics) may be efficacious without promoting antibiotic resistance.[A14]

Infection Control

Infection control programs of health care facilities (Chapter 261) should include practices to prevent catheter-associated UTI.[20] Evidence-based guidelines provide clear recommendations, including ongoing surveillance. The most important intervention is to avoid the use of an indwelling catheter wherever possible and, when there are clear indications for catheter use, to limit the duration to as short a time as possible. Meatal cleaning with chlorhexidine solution before catheter insertion can decrease the incidence of catheter-associated asymptomatic bacteriuria and UTIs.[A15] For adults who require intermittent self-catheterization, continuous antibiotic prophylaxis can reduce recurrent UTIs but at the risk of developing resistant organisms.[A16] The future development of biofilm-resistant materials may help reduce the problem of catheter-associated UTI.

PROGNOSIS

The prognosis of uncomplicated cystitis and pyelonephritis is good. Women with acute uncomplicated cystitis do not receive antimicrobial therapy, and symptoms will usually resolve by 1 to 2 weeks. Women with very frequent recurrent, acute uncomplicated UTI experience no long-term adverse outcomes, such as renal impairment or hypertension. A small proportion of women with severe presentations of acute nonobstructive pyelonephritis develop renal scars, but these are not associated with impaired renal function. Whether men also develop such scars is unknown. Patients with frequent recurrent complicated UTI may experience substantial morbidity with recurrent infections, but poor long-term medical outcomes are usually determined by the underlying abnormality rather than by infection. A perinephric abscess generally is cured by appropriate therapy and is not associated with long-term sequelae. Patients with urosepsis have a fatality rate of about 10%. Factors increasing the risk of death are advanced age and significant underlying diseases, as well as inadequate initial antimicrobial treatment.

264 APPROACH TO THE PATIENT WITH A SEXUALLY TRANSMITTED INFECTION

HEIDI SWYGARD AND MYRON S. COHEN

SEXUALLY TRANSMITTED INFECTIONS

DEFINITION

Sexually transmitted infections (STIs) include a wide variety of organisms that are transmitted through intimate contact involving skin or mucosal surfaces of the oropharynx, vagina, penis, and rectum.[1] STIs can generally be divided into five broad categories (syndromes): urethritis, genital ulcers, epithelial cell disorders, vaginal discharge, and ectoparasites (Table 264-1). Gender inclusive models (Chapter 215) and programs of care are recommended for all persons who would benefit from such services.

EPIDEMIOLOGY

The interaction between the host and the sexually transmitted pathogen plays a critical role, and characteristic tissue changes offer clues about etiology. Several sexually transmitted pathogens cause local inflammation only (*Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Trichomonas vaginalis*), with the potential for local tissue invasion (*N. gonorrhoeae*, *C. trachomatis*) or systemic dissemination (*N. gonorrhoeae*). Some sexually transmitted pathogens cause tissue ulceration (*Treponema pallidum*, *Haemophilus ducreyi*, herpes simplex viruses 1 and 2, *Klebsiella granulomatis*). Human papillomaviruses cause epithelial cell changes and predispose to neoplasm. Several sexually transmitted pathogens (human immunodeficiency virus [HIV], hepatitis B and C viruses, cytomegalovirus) routinely enter through the genital tract without causing any local changes.

Other important systemic diseases that can be acquired through sexual transmission include Zika virus, Ebola virus, Lassa fever, and monkeypox (Chapters 343, 351, and 352). Although these infections can present with genital cutaneous lesions that can be confused with herpes simplex virus, they can cause systemic signs and symptoms that can be fatal.

ABSTRACT

Sexually transmitted infections (STIs) include a wide variety of organisms that are transmitted through intimate contact involving skin or mucosal surfaces of the oropharynx, vagina, penis, and rectum and are among the most common infections worldwide. Many infections are subclinical and are generally transmissible whether they are symptomatic or asymptomatic. STIs play an important role in HIV transmission and remain an important public health challenge.

Sexually transmitted infections are among the most common infections worldwide, but most are never reported. The World Health Organization (WHO) estimates that nearly 1 million people worldwide become infected every day with any of four curable sexually transmitted infections: chlamydia, gonorrhea, syphilis, and trichomoniasis. Each year, an estimated 2.5 million incident cases of gonorrhea, chlamydia, and syphilis are reported in the United States alone.[2] However, the total estimated number of cases of all sexually transmitted infections is likely much greater because of under-reporting and because many infections are subclinical and may escape detection. Sexually transmitted infections are generally transmissible whether they are symptomatic or asymptomatic.

Despite efforts to control the epidemic of sexually transmitted infections, the numbers of new infections continue to grow. This epidemic disproportionately impacts specific populations and geographies, sometimes leading to long-term health consequences such as infertility, poor birth outcomes, cancer, and HIV infection. In the United States, social determinants of health contribute to an unequal burden of sexually transmitted infections in Black, American Indian/Alaska Native, and Latinx communities (Chapter 4).

Chlamydia (Chapter 294), gonorrhea (Chapter 275), and syphilis (Chapter 295) are reportable to the U.S. Centers for Disease Control and Prevention (CDC). Overall, primary and secondary syphilis rates have increased every year since 2000 and increased by 6.8% from 2019 to 2020. Although rates of syphilis are lower among women compared with men, rates in women have increased nearly 150% from 2016 to 2020, and rates of congenital syphilis increased by 250% during that time period. Men who have sex with men account for almost 60% of syphilis cases among men. For gonorrhea, the overall rate is about 150 cases per 100,000 population among women and 225 cases per 100,000 in men, but rates in men and women ages 20 to 24 years are closer to 750 cases per 100,000.

Emerging pathogens also must be considered in certain groups of patients. Some of these pathogens are asymptomatic but are of public health significance (e.g., Ebola [Chapter 351], Zika [Chapter 352] viruses in genital secretions), whereas others represent relatively newly recognized pathogens (e.g., *Neisseria meningitidis* urethritis [Chapter 274] and monkeypox [Chapter 343]).[3]

Seroprevalence data and national surveys suggest a high burden of viral sexually transmitted infections. Antibodies to herpes simplex virus 2 (HSV-2) are found in the serum of about 12% of the population (ages 14 to 49 years), with seropositivity more frequent in non-Hispanic Black Americans (about 35%) compared with non-Hispanic Whites (about 8%), and in women (about 16%) compared with men (about 8%).

The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) pandemic significantly impacted the availability of services for patients who have sexually transmitted infections, especially in urban settings. The longer-term ramifications of missed opportunities for screening and intervention remain to be seen.

The spread of sexually transmitted infections depends on the organism, the host, the length of time an infected person remains contagious, and the number of people exposed. These parameters can be summarized as:

$$R_o = B \times D \times C$$

where R_o is the basic reproductive rate of an infection, or the mean number of secondary cases a typical single infected person will cause in a population; B is the efficiency of transmission; D is the duration of infectiousness; and C is the number of sexual partners.

PATHOBIOLOGY

Sexually transmitted pathogens depend entirely on human-human transmission, although *T. vaginalis* may have some inanimate sources. The efficiency of transmission reflects the infectiousness of the index case (which depends on the concentration and phenotype of the organism in the genital tract) and the susceptibility of the sexual partner (which reflects the resistance of the host, whether it is hereditary, acquired, or innate). Because immunity to STIs is rare, reinfections are common, and vaccines have been developed only for hepatitis A, hepatitis B, and human papillomavirus.

Each sexually transmitted organism produces a characteristic syndrome because each pathogen has a proclivity for one or more tissues and, when symptomatic, can evoke a predictable inflammatory response. For example, gonococci (Chapter 275) that infect the male urethra generally produce an intense neutrophilic response that leads to a purulent discharge and pain with urination, whereas *C. trachomatis* (Chapter 294) is less likely to produce such a response in the same tissue and is more likely to produce a mild, watery discharge or no symptoms at all.

Because sexually transmitted infections are more prevalent in certain geographies and populations, coinfections are common. Detection of one sexually transmitted organism should lead to other tests. Sexually transmitted pathogens also can be synergistic: for example, sexually transmitted infections also contribute to the acquisition and transmission of HIV and hamper efforts to prevent its transmission. Genital ulcers disrupt the genital mucosal epithelium and allow the entry of HIV. Inflammation caused by ulceration recruits macrophages and lymphocytes, thereby increasing the number of target cells for HIV and the number of receptors per cell. Sexually transmitted infections also can increase the HIV viral load in genital secretions, including semen and vaginal secretions, thereby contributing to a greater risk of transmitting HIV.[4]

DIAGNOSIS

Syndromic Strategies

The syndromic approach focuses on diagnosis based on signs and symptoms, followed by empiric treatment of the index case and concomitant treatment of sexual partners. The syndromic approach is particularly critical in resource-constrained countries or wherever laboratory tests are not available or their cost is prohibitive. In the United States, microbiologic diagnosis is preferred because it confirms the choice of empiric therapy or redirects subsequent care; permits the detection and monitoring of resistance to treatment; and enables specific diagnoses to be reported to public health authorities, as is required by state law for many sexually transmitted infections.

Newer point of care nucleic acid amplification tests (NAATs) for sexually transmitted infections allow diagnosis and treatment for some syndromes (e.g., vaginitis)[5] and specific infections (e.g., gonorrhea and chlamydia) at the same outpatient visit. However, when test results are not available at the same visit, the most appropriate syndromic treatment should be provided empirically at the point of care to resolve the infection and to reduce subsequent transmission.

The diagnosis of a sexually transmitted infection suggests condomless intercourse and serves as a marker for potential HIV infection. Any person undergoing evaluation or treatment for an STI should be tested for HIV infection, because early diagnosis (Chapter 355) and treatment (Chapter 357) of HIV infection has major personal and public health benefits, including reducing secondary HIV transmission.[A1]

TREATMENT

General Approach

Although most sexually transmitted infections are self-limited and readily treated, the comprehensive and proper management of the patient with a sexually transmitted infection requires considerable skill. First, the correct syndrome must be recognized, and a decision about specific diagnostic tests must be made. Second, empiric therapy must be provided and must be sufficiently broad to promise cure or reduced duration of illness. Third, the clinician is obligated to search for other sexually transmitted infections of public health or personal significance. Fourth, the clinician must deal with the patient's sexual partners, through either referral or expedited partner therapy. Fifth, the patient needs counseling and adjunctive preventive measures, where appropriate. Such measures might include vaccination for hepatitis A, hepatitis B, or human papillomavirus or antimicrobials to prevent another sexually transmitted infection, such as incubating syphilis or HIV infection.

SEXUALLY TRANSMITTED INFECTION SYNDROMES

Urethritis

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Urethritis is characterized by some combination of urethral discharge and dysuria, but prostatitis (Chapter 114) can cause similar complaints. Women with urethritis typically have some combination of dysuria and pyuria, which must be differentiated from bacterial cystitis (Chapter 263).

Urethritis is diagnosed when one or more of the following are demonstrated: (1) mucopurulent or purulent urethral discharge, (2) Gram stain of urethral secretions demonstrating two or more leukocytes per oil immersion microscopic field, (3) positive leukocyte esterase test result on first-void urine, or (4) microscopic examination of first-void urine demonstrating 10 or more leukocytes per high-power field. If no urethral discharge can be expressed from the urethral meatus, a calcium alginate swab can be inserted 5 mm into the urethra; the material collected is transferred to a slide by rolling the swab along the glass.

Urethritis is caused by a limited group of pathogens (see Table 264-1) that may be difficult to visualize microscopically or to grow in culture. Nevertheless, specific diagnosis may enhance the management of sexual partners, and the results from such tests should be reported to the health department.

A Gram stain of urethral discharge is a simple and rapid diagnostic test to document both urethritis and possible gonococcal infection (Chapter 275), which is characterized by the detection of leukocytes containing intracellular gram-negative diplococci (Fig. 275-1). Because confirmation of gonococcal urethritis does not exclude concomitant infection with *Chlamydia* or *Mycoplasma*, NAATs, which are highly sensitive and specific for the detection of these and other organisms, are routinely performed on the urethral discharge owing to the high probability of coinfection. However, clinicians should use caution in relying solely on NAATs for diagnosing gonorrhea because it does not always identify other sexually transmitted *Neisseria* species, such as *Neisseria meningitidis*.

Nucleic acid amplification tests for gonorrhea, *Chlamydia*, and *Trichomonas* also can be applied to first-void urine samples (the meatus is intentionally not cleaned so that the urine is contaminated with these organisms), urethral swab material, or vaginal swab material.[6] Extra-genital (e.g., rectal and throat swabs) NAATs are recommended for men who have sex with men or women with reported exposures, since urine-based and cervicovaginal testing alone can miss a large proportion of infected individuals.[7]

TREATMENT

In practice, patients and (in most cases) sexual partners must be treated with empiric therapy to cover the spectrum of potentially causative organisms before the results of definitive tests are available. This empiric treatment should be initiated as soon as possible after the clinical diagnosis and should be directly observed if feasible (Table 264-2).[8,9] Doxycycline appears to be more effective than azithromycin for nongonococcal urethritis and is now the preferred treatment for chlamydia because of the increasing resistance of other concomitant infections (e.g., gonorrhea and *M. genitalium*) to macrolides.

If NAAT results suggest that empiric therapy is unlikely to be successful or if the patient fails to respond to empiric therapy, the antibiotic regimen must be adjusted. For *M. genitalium*, persistent or recurrent urethritis should be treated with moxifloxacin for 7 days. *T. vaginalis*, which also should be considered in the setting of treatment failure, is susceptible to metronidazole or tinidazole. Because treatment for urinary tract pathogens (Table 263-6) may also resolve sexually transmitted urethritis, the clinician who is treating a presumed bladder infection should consider a possible sexually transmitted infection as well.

For presumed sexually transmitted proctitis, the recommended empiric treatment is ceftriaxone (500 mg IM once) plus doxycycline (100 mg orally twice daily for 7 days). For presumed sexually transmitted epididymitis, ceftriaxone (500 mg IM once) plus doxycycline (100 mg orally twice daily for 10 days) is recommended in heterosexual men, but ceftriaxone (500 mg IM once) plus levofloxacin (500 mg orally daily for 10 days) is preferred in men with suspected epididymitis due to enteric pathogens.

TABLE 264-2 SYNDROMIC TREATMENT OF URETHRITIS

GONOCOCCAL*
Recommended
Ceftriaxone 500 mg injected intramuscularly once, *and* (if chlamydia has not been excluded) doxycycline 100 mg orally twice daily for 7 days (for persons weighing >150 kg, the ceftriaxone dose should be 1 g)
NONGONOCOCCAL
Recommended
Doxycycline 100 mg orally twice daily for 7 days
Alternative
Azithromycin 1 g orally as a single dose; or 500 mg orally as a single dose followed by 250 mg orally daily for 4 days
Recurrent or Persistent
If azithromycin was used for initial episode: moxifloxacin 400 mg orally once daily for 7 days If doxycycline was used for initial episode: azithromycin 1 g orally (single dose) *PLUS* For men who have sex with women who live in areas where *T. vaginalis* is highly prevalent: Metronidazole 2 g orally (single dose) *or* Tinidazole 2 g orally (single dose)

*Uncomplicated anorectal and genital disease.

GENITAL ULCERS

In the United States, HSV-1 and HSV-2 (Chapter 345) and *T. pallidum* are responsible for virtually all genital ulcers, and HSV-1 and HSV-2 are by far the most common cause.

GENITAL HERPES

Genital herpes (Chapter 345), which usually develops after an incubation period of less than 21 days, arises as clustered vesicles on an erythematous base. The vesicles become pustular and then rupture to form shallow, painful ulcers that may coalesce. The ulcers heal by crusting over, and the process is usually completed 2 to 3 weeks after the initial lesions appear. In the recent monkeypox outbreak, the lesions were initially confused with the vesicles of herpes simplex virus. Recurrences proceed through the same stages but generally persist only about 5 to 7 days. The first (incident) episode of HSV-2 infection may be accompanied by systemic signs and symptoms including fever and headache, the latter reflecting the spread of HSV to the central nervous system. HSV-2 can cause recurrent meningitis that may occur coincident with reactivation of the genital lesions.

About 20% of infected individuals manifest the classic genital presentation, 60% have mild and atypical signs and symptoms, and the remaining 20% are completely asymptomatic. Viral shedding occurs more often in symptomatic individuals (20% of days) compared with asymptomatic individuals (10% of days), thereby posing an ongoing risk to sexual partners. Nucleic acid testing of swabs of lesions has a 97% sensitivity for detecting herpes virus.[10] However, serologic screening for genital herpes is associated with a high rate of false-positive test results and potential psychosocial harms. Treatment with antiviral medications can shorten the duration of symptoms and may be helpful for

TABLE 264-3 TREATMENT FOR GENITAL ULCERS

GENITAL HERPES
First Episode
Acyclovir 400 mg orally 3 times/day for 7-10 days *or* Famciclovir 250 mg orally 3 times/day for 7-10 days *or* Valacyclovir 1 g orally 2 times/day for 7-10 days (Treatment can be extended if healing is incomplete after 10 days of therapy.)
Recurrent Episodes of HSV-2
Acyclovir 800 mg orally 2 times/day for 5 days *or* Acyclovir 800 mg orally 3 times/day for 2 days *or* Famciclovir 1 g orally 2 times/day for 1 day *or* Famciclovir 500 mg orally once, followed by 250 mg 2 times/day for 2 days *or* Famciclovir 125 mg 2 times/day for 5 days *or* Valacyclovir 500 mg orally 2 times/day for 3 days *or* Valacyclovir 1 g orally once daily for 5 days
Chronic Suppression of HSV-2
Acyclovir 400 mg orally 2 times/day *or* Valacyclovir 500 mg orally once a day *or* Valacyclovir 1 g orally once a day *or* Famciclovir 250 mg orally 2 times/day
SYPHILIS
Primary or Secondary
Benzathine penicillin G 2.4 million units IM in a single dose
Latent
Early latent syphilis: Benzathine penicillin G 2.4 million units IM in a single dose *Late latent syphilis:* Benzathine penicillin G 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1-week intervals
LYMPHOGRANULOMA VENEREUM
Doxycycline 100 mg orally 2 times/day for 21 days
Alternative Regimens
Azithromycin 1 g orally once weekly for 3 weeks *or* Erythromycin base 500 mg orally 4 times/day for 21 days
CHANCROID
Azithromycin 1 g orally in a single dose *or* Ceftriaxone 250 mg IM in a single dose *or* Ciprofloxacin 500 mg orally 2 times/days for 3 days *or* Erythromycin base 500 mg orally 3 times/day for 7 days
GRANULOMA INGUINALE (DONOVANOSIS)
Azithromycin 1 g orally once weekly or 500 mg daily for >3 weeks and until all lesions have completely healed
Alternative Regimens
Doxycycline 100 mg orally 2 times/day for at least 3 weeks and until all lesions have completely healed *or* Erythromycin base 500 mg orally 4 times/day for >3 weeks and until all lesions have completely healed *or* Trimethoprim-sulfamethoxazole one double-strength (160 mg/800 mg) tablet orally 2 times/day for >3 weeks and until all lesions have completely healed

HSV = herpes simplex virus; IM = intramuscular.

preventing recurrence of HSV-2 (Table 264-3). Counseling for patients should include a discussion of the risk of shedding, disclosure, and the avoidance of sex in the viral prodrome or during outbreaks.

SYPHILIS

The ulcerative lesion of syphilis (Chapter 295 and Fig. 295-1)—the chancre—is indurated and typically painless. Some patients may have multiple ulcers rather than a single chancre. Swabs from a genital ulcer should be collected and examined by dark-field microscopy; the finding of motile spirochetes is diagnostic for syphilis. When darkfield microscopy is not available, primary syphilis can be diagnosed with serologic testing, but the nontreponemal and treponemal antibody tests may be negative in early primary infection. Secondary syphilis results when the spirochetes spread systemically, thereby leading to a characteristic maculopapular rash involving the palms and soles, alopecia, oral mucous patches, or condyloma latum.[11]

All patients who present with a sexually transmitted infection must have serologic screening (E-Fig. 264-1) for syphilis. (e.g., rapid plasma reagin test, Venereal Disease Research Laboratory [VDRL] test, toluidine red unheated serum test [TRUST]). If reactive, the diagnosis must be confirmed with a more specific treponemal antibody test (microhemagglutination assay–*T. pallidum*, fluorescent treponema antibody test). However, some large laboratories have switched to the reverse syphilis screening algorithm using newer automated treponemal tests for initial testing followed by a nontreponemal test (Chapter 295).

All patients diagnosed with syphilis should be questioned about ocular symptoms and symptoms suggestive of neurosyphilis; ocular and neurosyphilis require 14 days of intravenous aqueous penicillin G (Table 295-4). Late latent syphilis and syphilis of unknown duration are managed with three weekly injections of intramuscular penicillin.[12]

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum,[13] caused by a serovar of *C. trachomatis* (Chapter 294), is characterized by local lymph node suppuration, ulceration with subsequent fibrosis, the formulation of fistulas, and distal edema. Lymphogranuloma venereum can manifest as a syndrome mimicking proctocolitis with clinical findings of rectal discharge (mucoid or hemorrhagic in appearance), tenesmus, anal pain, constipation, and fever. Untreated, it can cause extensive local damage with fistulization and stricture formation. Secondary bacterial infections, some of which may be invasive, may occur. Outbreaks among men who have sex with men have been reported in the United States and Europe.

CHANCROID AND GRANULOMA INGUINALE

Chancroid (Chapter 276) infection with *H. ducreyi* produces painful, ragged ulcers and tender inguinal lymphadenopathy, which may be fluctuant. Unlike the lesions of HSV infection, these genital ulcers are likely to vary in size.

Granuloma inguinale (Chapter 292), which is caused by *Klebsiella granulomatis*, is also known as donovanosis. The disease is rare in the United States The ulcerative lesions are painless and vascular, with a beefy red appearance. The disease is slowly progressive with regional lymphadenopathy. Diagnosis is made by identification of dark staining Donovan bodies on crush biopsy or tissue preparations.

TREATMENT

Treatment is based on the specific cause (Table 264-3).

EPITHELIAL CELL INFECTIONS

HUMAN PAPILLOMAVIRUS

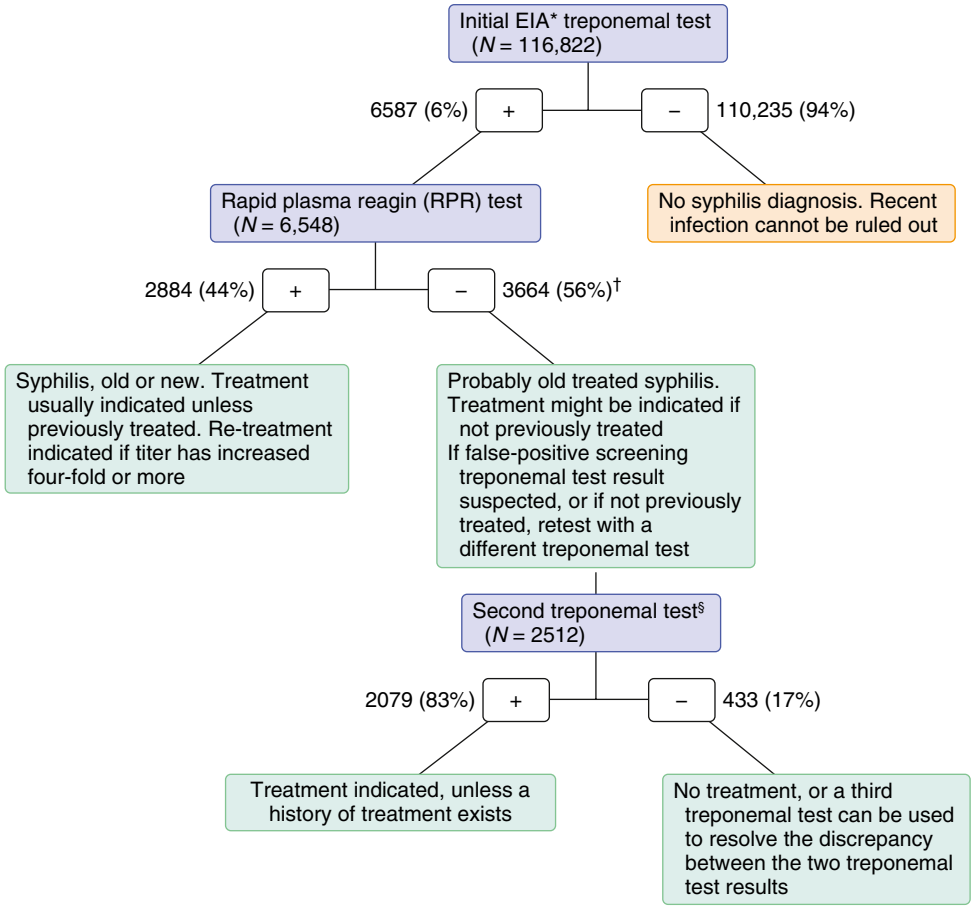
Sexually transmitted human papillomavirus infection (Chapter 344) is generally transient and asymptomatic, but some patients develop visible genital warts. These warts are painless, soft, moist, pink- or flesh-colored swellings that vary in shape and can be raised or flat, single or multiple, small or large, and sometimes cauliflower shaped. Warts occur in the vulva, vagina, and anus; on the cervix; and on the penis, scrotum, groin, or thigh. Genital warts are diagnosed by visual inspection.

TREATMENT AND PREVENTION

Treatment is directed at the local lesions, with topical agents (e.g., patient-applied imiquimod 3.75% or 5% cream or podofilox 0.5% solution or gel; or clinician-administered trichloroacetic acid or bichloroacetic acid 80-90% solution), cryotherapy, or surgical removal. However, such treatment generally is not curative.

Two oncogenic human papillomavirus genotypes (16 and 18) are responsible for almost all anogenital, cervical, and oropharyngeal cancers and precancerous lesions. Human papillomavirus types 6 and 11 are responsible for most cases of genital warts and recurrent respiratory papillomatosis. Papanicolaou smears are recommended for sexually active women beginning at the age of 21 years, regardless of risk factor or age at coitarche (Chapter 184). However, specific testing for human papillomavirus is not recommended for women younger than 30 years. The frequency of rescreening is influenced by age, previous screening results, and prior test results. Male gender, smoking, and HIV-positive status are significantly associated with prevalent oral human papillomavirus.

Three human papillomavirus vaccines (Chapter 15) are currently approved by the U.S. Food and Drug Administration for use in males and females: a quadrivalent vaccine (protecting against types 6, 11, 16, and 18), a bivalent vaccine (protecting against types 16 and 18), and a 9-valent vaccine (6, 11, 16, and 18, 31, 33, 45, 52, and 58). Vaccination (Table 344-2) is recommended for males and females ages 26 years and younger, including previously unvaccinated, immunocompromised persons (e.g., HIV).



E-FIGURE 264-1. **The reverse syphilis testing algorithm using treponemal tests for initial screening.** *Enzyme immunoassay. †Reactive with EIA treponemal test but nonreactive with RPR test. §Using *Treponema pallidum* particle agglutination or fluorescent treponemal antibody tests. (Redrawn from the Centers for Disease Control and Prevention. Syphilis testing algorithms using treponemal tests for initial screening—four laboratories, New York City, 2005-2006. *MMWR Morb Mortal Wkly Rep*. 2008;57:872-875.)

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum (Chapter 343) is a generally a benign skin condition that is characterized by small raised lesions (called mollusca) that may be white, pink, or flesh-colored and may have a pearly appearance. Lesions can be distinguished from warts by the dimple or pit seen in the center. Molluscum is spread by skin-to-skin contact or contact with fomites contaminated by the virus (e.g., towels, pool toys). The lesions may occur anywhere on the body, including the genital area. Molluscum contagiosum is usually self-limited in healthy individuals, with lesions resolving in 6 to 12 months without scarring. Lesions in the genital area may require treatment (physical removal or oral or topical therapy; see Chapter 343). Immunocompromised patients may not respond to traditional treatment, and referral to a specialist may be warranted.

FEMALE GENITAL DISCHARGE

Infections of the female genitourinary tract produce several syndromes with overlapping symptoms (dysuria, vaginal discharge, vulvar irritation), the cause of which can usually be established with a careful history, examination, and laboratory tests. The initial approach depends on the primary anatomic site of infection—urinary tract, endocervix, or vagina. The columnar epithelium of the endocervix is susceptible to infection with *N. gonorrhoeae*, *C. trachomatis*, and *T. vaginalis*, and the vagina is susceptible to infection with *Candida albicans*, *T. vaginalis*, and the syndrome of bacterial vaginosis. The cervix may appear completely normal in women with cervical infection, but mucopurulence at the cervical os or mucosal friability suggests infection. Vaginitis is associated with a visible discharge, and the characteristics of the vaginal fluid offer diagnostic clues.

Female genital discharge is a condition in which syndromic management strategies generally lack sensitivity and specificity. Microscopic examination of a wet mount preparation of vaginal secretions may enhance the effectiveness of syndromic treatment, but interpretation of results is difficult and cannot exclude infection with several pathogens concurrently.

BACTERIAL VAGINOSIS

Bacterial vaginosis, which is the most common cause of vaginal discharge in the United States, is an anaerobic polybacterial dysbiosis of the vaginal microbiome (i.e., a vaginal microbiome not dominated by lactobacilli).[14] Women with bacterial vaginosis are often minimally symptomatic but may note mild vaginal discharge and vaginal odor (which is often increased after coitus).[15] The normal vaginal flora contains hydrogen peroxide–producing lactobacilli such as *Lactobacillus crispatus* and *Lactobacillus jensenii*, which probably help "defend" the vagina against a number of pathogens (an example of innate immunity). *Lactobacillus acidophilus* is rarely found in the normal vagina, so yogurt cannot serve as a remedy or a preventive agent.

Bacterial vaginosis begins with the unexplained disappearance of the normal vaginal flora and its replacement with *Gardnerella vaginalis* and many species of anaerobic bacteria. The precise mechanism causing this shift in vaginal flora (i.e., dysbiosis) is poorly understood, but *G. vaginalis, Prevotella bivia*, and other organisms may be early colonizers that lead to the subsequent development of a biofilm followed by secondary colonization.[16] Bacterial vaginosis is not necessarily a benign change in flora. It is associated with an increased rate of upper tract infection (endometritis, salpingitis) and complications of pregnancy, including premature rupture of the membranes, preterm delivery, and infertility.[17] Women with bacterial vaginosis may have increased risk for the acquisition of HIV; male partners may be at increased risk of HIV infection as well.

The discharge of bacterial vaginosis is homogeneous and may contain bubbles. Vaginal pH is elevated above the normal 4.0 to 4.5. Adding 10% potassium hydroxide to the vaginal discharge on the microscope slide or to the discharge present in the extracted speculum elicits an amine-like, fishy odor, yielding a positive "whiff" test result because of the elaboration of amines from the anaerobic flora. Examination of vaginal material as a wet mount reveals the absence of bacilli and their replacement with clumps of coccobacilli. Some vaginal epithelial cells are coated with coccobacilli, which may obscure their edges (clue cells) or the normally clear appearance of the cytoplasm, sometimes described as looking like a fried egg that has been salted and peppered. Relatively few polymorphonuclear leukocytes are observed; large numbers of leukocytes in the wet mount of a woman with bacterial vaginosis suggest a coincident infection, possibly trichomoniasis or bacterial cervicitis.

TREATMENT

Treatment of asymptomatic women who are not at high risk for preterm delivery appears to confer no benefit. For symptomatic women, treatment against the anaerobic flora consists of metronidazole (500 mg orally twice daily for 7 days or 0.75% gel at 5 g intravaginally daily for 5 days), secnidazole (2 g of oral granules in a single dose), tinidazole (2 g orally daily for 2 days or 1 gram orally once daily for 5 days), or clindamycin (2% cream as 5 g intravaginally at bedtime for 7 days, 300 mg orally twice daily for 7 days, or 100 mg ovules intravaginally at bedtime for 3 days). The relapse rate is about 30%, and treatment of male sexual partners offers no benefit. However, *Lactobacillus crispatus* CTV-05 administered vaginally can significantly reduce recurrences of bacterial vaginosis after treatment with vaginal metronidazole gel.[A2]

VAGINITIS

Candidiasis

Vulvovaginal candidiasis (Chapter 310) is common and is seen when endogenous *Candida* species outgrow normal bacterial flora, most frequently in women who are taking antibiotics or using oral contraceptives. Women usually complain of vulvar itching and discomfort and may or may not notice an accompanying discharge. The vagina generally maintains normal numbers of lactobacilli, so the vaginal pH is usually normal, which is helpful in discriminating candidiasis from other vaginal infections. The labia and vaginal walls may be erythematous. Although classically described as "curdy," the discharge of candidiasis is frequently loose and is difficult to distinguish from other discharges. Vaginal material may be treated with 10% potassium hydroxide to destroy other cellular elements and to make the fungi easier to observe. Wet mount, however, has a sensitivity of only about 50%, and a woman with a classic clinical presentation should be treated even if fungal elements are not observed.[18]

TREATMENT

A wide range of topical antifungal medications (Table 264-4) are available (many without a prescription), and all these drugs are approximately equally effective, although the cure rate with some single-dose topical treatments appears to be lower than rates with longer regimens. Fluconazole administered as a single oral dose of 150 mg is highly effective. Infection with yeasts other than *C. albicans* may require longer therapy. Recurrent vulvovaginal candidiasis is a problem for many women, and optimal management has not been defined. Oteseconazole (150 mg orally daily for 7 days, then once weekly for 11 weeks) is a newer option.[A3] Maintenance antifungal regimens with oral fluconazole may be considered. Recurrent infection should lead the clinician to consider underlying diabetes mellitus or HIV infection. Treatment of sexual partners of women with candidiasis confers no benefit.

Trichomoniasis

The estimated annual incidence of *Trichomonas vaginalis* (Chapter 324) worldwide exceeds that of chlamydia and gonorrhea combined. Women with *T. vaginalis* infection may complain of purulent discharge and vulvar irritation. The vaginal walls are red, and the vagina may contain excessive yellow or green

TABLE 264-4 SELECTED TOPICAL ANTIFUNGAL AGENTS FOR VAGINAL CANDIDIASES

CREAMS
Over-the-Counter
Clotrimazole (2% cream): 5 g intravaginally daily for 3 days Miconazole (4% cream): 5 g intravaginally daily for 3 days
Prescription
Butoconazole (2% cream): 5 g intravaginally once Terconazole (0.8% cream): 5 g intravaginally daily for 3 days
SUPPOSITORIES
Over-the-Counter
Miconazole (1,200 mg) once
Prescription
Terconazole 80 mg vaginal suppository daily for 3 days

Source: https://www.cdc.gov/std/treatment-guidelines/STI-Guidelines-2021.pdf.

discharge that is bubbly or frothy in appearance. The ectocervix may also be inflamed or have punctate microhemorrhages, thereby causing the pathognomonic "strawberry cervix" (colpitis macularis). Vaginal pH is elevated, but the whiff test result is generally negative. Wet mount reveals large numbers of polymorphonuclear leukocytes as well as motile protozoa about the same size as the leukocytes, with visible flagella; motile organisms may be recognized in about two thirds of cases. Because of poor performance of wet mount microscopy, nucleic acid testing is recommended.

TREATMENT

A 7-day course of metronidazole (500 mg twice daily) is the preferred treatment in women, but a single 2-g dose can be used in men.[19] Tinidazole (2 g orally in a single dose) is an alternative, but resistance to both regimens is increasing. Drug-resistance testing can be performed through the CDC; treatment recommendations based on resistance testing may include higher doses and a longer duration of tinidazole or metronidazole under expert guidance.

CERVICITIS

The clinical diagnosis of cervicitis is suggested by tenderness on bimanual examination, visible inspection revealing inflammation, or discharge. The specific diagnosis can be made only by detecting microorganisms from the cervix, preferably by nucleic acid testing of the discharge. *N. gonorrhoeae* and *C. trachomatis* have tropism for cervical tissue, whereas other pathogens (including HIV) can apparently infect the vaginal tissues as well.

TREATMENT

Ideally, treatment should be based on test results. Recommended treatment is doxycycline (100 mg orally twice daily for 7 days) or a single dose of azithromycin (1 g orally) for chlamydia, doxycycline (100 mg orally twice daily for 7 days) followed by moxifloxacin (400 mg once daily for 7 days) for *Mycoplasma genitalium*, and ceftriaxone (500 mg IM once) if gonococcal infection is detected or the risk for it is high. If follow-up cannot be ensured or NAAT testing is not available, empiric treatment targeted to both *C. trachomatis* and *N. gonorrhoeae* should be used for women at high risk (age < 25 years, new sexual partner, sexual partner with a sexually transmitted disease, or partners who also have other partners).

PELVIC INFLAMMATORY DISEASE

Each year, more than 800,000 women develop pelvic inflammatory disease (PID) in the United States.[20] The bacterial causes of pelvic inflammatory disease are myriad and include *N. gonorrhoeae*, *C. trachomatis* (about 35% of cases),[21] and *Mycoplasma* (especially *M. genitalium*); other anaerobic and aerobic bacteria that colonize the vagina and cytomegalovirus (Chapter 347) also have been implicated. Infection ascends from the cervix into the uterine cavity, thereby producing endometritis, occasionally with extension to the fallopian tubes, causing salpingitis. Some intrauterine devices have been associated with an increased risk of salpingitis, and some data suggest that vaginal douching is a predisposing factor.

Women with pelvic inflammatory disease often complain of pelvic pain, which may be constant or intermittent and is typically exacerbated by menses and coitus. Adnexal tenderness on bimanual examination leads to the clinical diagnosis of salpingitis. Fever, cervical tenderness, leukocytosis, and an elevated sedimentation rate are sometimes observed. Severe signs or symptoms suggest a tubal abscess or spread of the infection to the upper genital tract.

The clinical diagnosis is confirmed laparoscopically in only about 70% of cases, thereby suggesting considerable error in diagnosis. Vaginal ultrasonography or computed tomography is often helpful in defining the cause of pelvic pain syndromes. Pregnant women with evidence of salpingitis should be hospitalized. Other indications for hospitalization include nonresponse to or intolerance of an oral regimen, presence of a tubo-ovarian abscess, and inability to exclude a surgical emergency, such as appendicitis.[22]

TREATMENT

Treatment should include therapy directed at anaerobes (Chapter 273; Table 264-5),[A4] but no conclusive evidence indicates that any one recommended antibiotic regimen is safer or more effective than the other recommended options.[A5] Chlamydial salpingitis may be mild, and patients may not seek medical attention, but empirically adding initial doxycycline (100 mg orally twice daily for 7 days) treatment for chlamydia may improve the outcomes of patients with pelvic inflammatory disease.[23] Intrauterine devices, if present, should be removed if clinical improvement does not occur.

TABLE 264-5 RECOMMENDED REGIMENS FOR PELVIC INFLAMMATORY DISEASE

OUTPATIENT WITH MILD TO MODERATE DISEASE
Ceftriaxone (500 mg IM in a single dose: for persons weighing ≥150 kg, 1 g of ceftriaxone should be administered) PLUS doxycycline (100 mg orally 2 times/day for 14 days) PLUS metronidazole (500 mg orally 2 times/day for 14 days) *or*
Cefoxitin (2 g IM in a single dose) and probenecid (1 g orally administered concurrently in a single dose) PLUS doxycycline (100 mg orally 2 times/day for 14 days) PLUS metronidazole (500 mg orally 2 times/day for 14 days) *or*
Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime) PLUS doxycycline (100 mg orally 2 times/day for 14 days) PLUS metronidazole (500 mg orally 2 times/day for 14 days)
INPATIENT WITH MODERATE TO SEVERE DISEASE
Ceftriaxone (1 g IV every 24 hours) PLUS doxycycline (100 mg orally or IV every 12 hours) PLUS metronidazole (500 mg orally or IV every 12 hours) *or*
Cefotetan (2 g IV every 12 hours) PLUS doxycycline (100 mg orally or IV every 12 hours) *or*
Cefoxitin (2 g IV every 6 hours) PLUS doxycycline (100 mg orally or IV every 12 hours)

IM = intramuscular; IV = intravenous.

PROGNOSIS

Women should experience some clinical improvement within about 72 hours of initiation of therapy. Failure to improve is an indication for hospitalization for treatment with ceftriaxone (1 gram IV q 24 hours), doxycycline (100 mg orally or IV every 12 hours), and metronidazole (500 mg IV or orally every 12 hours). Alternative treatment regimens should include doxycycline (100 gm IV or orally every 12 hours) plus either cefotetan (2 grams IV every 12 hours) or cefoxitin (2 grams IV every 6 hours). With clinical improvement, patients may be transitioned to oral therapy with doxycycline 100 mg orally twice daily) and metronidazole (500 mg orally twice a day) to complete a total of 14 days of therapy.

Ectopic pregnancy, tubo-ovarian abscess, and infertility are complications of salpingitis. Infertility complicates approximately 15% of initial attacks of salpingitis, but the infertility rate after three or more episodes of salpingitis approaches 75%.

ECTOPARASITES

Ectoparasitic infection include pubic lice and scabies (Chapter 98). Scabies is caused by the mite *Sarcoptes scabiei* and can result in intense pruritus. Patients with pubic lice may present with symptoms of itching or note seeing nits or lice in their pubic hair.

Visualization of nits or lice confirms the diagnosis, as does identification of burrows in affected skin. Microscopic visualization of skin scrapings from affected areas can demonstrate mites, eggs, or feces, but this method is often low yield. Treatment for both conditions is local application of cidal agents or oral ivermectin (Table 264-6).

PREVENTION

Sexually transmitted infections are preventable. The U.S. CDC recommends five strategies as the foundation for an effective prevention program: (1) education and counseling of persons at risk to motivate the adoption of safer sexual behavior; (2) identification of asymptomatic infected persons and symptomatic persons unlikely to seek diagnostic and treatment services; (3) rapid and effective diagnosis and treatment of infected persons; (4) evaluation, treatment, and counseling of exposed sexual partners; and (5) preexposure vaccination of persons at risk for vaccine-preventable STIs.

Behavioral Interventions

Abstaining from sexual intercourse or being in a long-term, mutually monogamous relationship with an uninfected partner is the most reliable way to prevent sexually transmitted infections. Abstinence should be recommended during treatment for a sexually transmitted infection. Both partners should be tested for sexually transmitted infections, including HIV infection, before initiating sexual intercourse.

Counseling is essential for people with sexually transmitted infections.[24] Interactive counseling, video presentations, peer groups, and other formats that emphasize the correct use of a condom can reduce the incidence of subsequent infections by 25 to 40%.[A6] HIV testing should be offered to anyone

TABLE 264-6 TREATMENTS FOR PUBIC LICE AND SCABIES

LICE
Permethrin 1% cream rinse applied to affected areas and washed off after 10 minutes *or* Pyrethrin with piperonyl butoxide applied to the affected area and washed off after 10 minutes
Alternative Regimens
Malathion 0.5% lotion applied to affected areas and washed off after 8-12 hours *or* Ivermectin 250 μg/kg body weight orally, repeated in 7-14 days
SCABIES
Permethrin 5% cream applied to all areas of the body from the neck down and washed off after 8-14 hours *or* Ivermectin 200 μg/kg body weight orally, repeated in 14 days (oral ivermectin has limited ovicidal activity; a second dose is required for eradication) *or* Ivermectin 1% lotion applied to all areas of the body from the neck down and washed off after 8-14 hours; repeat treatment in 1 week if symptoms persist
Alternative Regimens
Lindane 1% 1 oz of lotion or 30 g of cream applied in a thin layer to all areas of the body from the neck down and thoroughly washed off after 8 hours (infants and children age <10 years should not be treated with lindane)

Source: https://www.cdc.gov/std/treatment-guidelines/STI-Guidelines-2021.pdf.

TABLE 264-7 RECOMMENDED REGIMEN FOR SURVIVORS OF A SEXUAL ASSAULT

ALL SEXUAL ASSAULT SURVIVORS
Postexposure prophylaxis recommendations for human immunodeficiency virus should be made on a case by case basis according to risk
FEMALES
Ceftriaxone (500 mg IM in a single dose; 1 g of ceftriaxone for persons weighing ≥150 kg) PLUS doxycycline (100 mg 2 times/day orally for 7 days) PLUS metronidazole (500 mg 2 times/day orally for 7 days)
MALES
Ceftriaxone (500 mg IM in a single dose; 1 g of ceftriaxone for persons weighing ≥150 kg) PLUS doxycycline (100 mg 2 times/day orally for 7 days)

IM = intramuscular.

diagnosed with a sexually transmitted infection and should be offered as an opt-out; separate written consent is not required. Further, HIV preexposure prophylaxis is an important HIV risk reduction tool that may be appropriate for sexually active adolescents and adults.

Barrier Methods

When used consistently and correctly, male latex condoms are effective in preventing the sexual transmission of HIV infection and can reduce the risk of other STIs (gonorrhea, chlamydia, and trichomoniasis). However, because condoms do not cover all exposed areas, they are likely to be more effective in preventing infections transmitted by fluids from mucosal surfaces (e.g., gonorrhea, chlamydia, trichomoniasis, HIV infection) than in preventing those transmitted by skin-to-skin contact (e.g., HSV, HPV, syphilis, chancroid). Failure of male condoms usually results from inconsistent or incorrect use rather than from breakage. Nonlatex condoms (those made of polyurethane or other synthetic material) can be used by persons with latex allergy. Less information is available on the effectiveness of female condoms to reduce the incidence of STIs. Although cervical caps and diaphragms cover the cervix, there is little evidence that they can prevent STIs or HIV infection.

Male Circumcision

Male circumcision reduces the amount of mucosal tissue that is susceptible to HIV and sexually transmitted pathogens. Circumcision of adult men reduces the acquisition of HIV by more than 70% for up to 5 years after circumcision (Chapter 356).[A7] Circumcision also appears to reduce the acquisition of other viral sexually transmitted pathogens, including HSV-2 and human papillomavirus.

Partner Services

The detection of a sexually transmitted infection demands consideration of the infected person's sexual partners, who may have undetected and serious disease. In addition, if partners are not treated, reinfection of the index case can be expected. The probability that a sexual partner is also infected reflects the efficiency of transmission of the sexually transmitted pathogen. Empiric partner therapy is recommended for syphilis, *N. gonorrhoeae, C. trachomatis, T. vaginalis*. Additionally, empiric partner therapy is indicated for the clinical syndromes of urethritis, cervicitis, and ectoparasites. Exceptions to empiric partner treatment include herpes simplex virus, human papillomavirus, and candidiasis. For example, most men with gonococcal urethritis infect their partners, whereas only about 50% of patients with HIV infection have infected their partners at the time of outreach. Partners who differ in terms of their infection status are referred to as discordant.

Sexual partners can be notified directly by the infected person or by health care workers, sometimes through proactive contact tracing. In general, dependence on the infected person is a less reliable way to get partners treated. However, in many states it is legal to pursue expedited care by providing the infected patient with the appropriate treatment for his or her partners. Expedited partner care is recommended for the treatment of gonorrhea and chlamydia infections.

Preexposure Interventions

Preexposure vaccination is the most effective method for preventing the transmission of certain sexually transmitted infections. For example, because hepatitis B virus is frequently transmitted sexually, hepatitis B vaccination (Chapters 15 and 134) is recommended for all unvaccinated persons being evaluated for a sexually transmitted infection. In addition, hepatitis A vaccine (Chapters 15 and 134) is recommended for men who have sex with men and for drug users (both injection and noninjection). Vaccines for human papillomavirus (Chapters 15 and 344) demonstrate continued high rates of protection in women, and they protect men and women against precancerous lesions.

Preexposure prophylaxis with daily oral therapy can prevent HIV (Chapter 356), but only in the setting of high-level (>85%) medication adherence. Neither topical microbicides[A8] nor antibacterial mouthwash[A9] have been effective for preventing sexually transmitted herpes virus or bacterial infections. On demand preexposure prophylaxis is effective in men who have sex with men, and in transgender women,[A10] but its use is not appropriate for persons engaging in vaginal sex. Long-acting options, such as injectable cabotegravir 600 mg IM every two months (following an initial loading dose of 2 injections delivered one month apart), may be an attractive option for sexually active adults and adolescents at risk for sexually acquired HIV infection.[A11]

Postexposure Prophylaxis

After consensual or nonconsensual sexual exposure, a variety of sexually transmitted infections can be prevented with empiric antibiotics (Table 264-7). For example, for men who have sex with men, doxycycline prophylaxis (100 mg or 200 mg) can reduce transmission of syphilis and bacterial sexually transmitted infections.[A12] Prevention of HIV infection following a potential exposure requires antiretroviral agents used in combination (two nucleoside reverse transcriptase inhibitors and one integrase inhibitor) that must be initiated shortly after the exposure (<72 hours) and used for 28 days (Chapter 356).

Contraception

All methods of birth control can influence the acquisition and outcome of a sexually transmitted infection. For example, oral contraceptive pills, implants, injections, and copper intrauterine devices[A13] do not intrinsically increase the risk of HIV infection themselves, but use of any birth control option may be associated with more sexual activity and hence higher risk for HIV or any other sextually transmitted infection. In addition, pregnancy itself (in the absence of effective birth control) affects the risk of acquiring a sexually transmitted infection as well as the health of the pregnancy and the neonate. Accordingly, the management of sexually transmitted infections demands consideration of the reproductive health of both partners as well as family planning issues.

TABLE 265-1 THE PRETRAVEL CONSULTATION WITH A TRAVELER TO THE DEVELOPING WORLD—A STRUCTURED APPROACH

PERFORM RISK ASSESSMENT
The following must always be ascertained initially to determine the appropriate preventive medical recommendations. Preprinted medical record forms may be used to record these.
Exact itinerary, including regions within each country to be visited
Dates of travel to assess risk of seasonal diseases
Age
Past vaccination history
Underlying illnesses
Current medications
Pregnancy status
Allergies
Purpose of trip
Risk exposures—blood, body fluids, adventure, or extensive outdoor exposures
Urban versus rural travel
Type of accommodations
Level of aversion to risk
Review traveler-specific risk with respect to emerging infectious pathogens
Financial limitations that may necessitate prioritization of interventions
ADMINISTER IMMUNIZATIONS
Administer routine vaccinations that are not up to date.
Administer indicated travel vaccines.
Provide to patient legally mandated Vaccine Information Statements from the Centers for Disease Control and Prevention (http://www.cdc.gov/vaccines/pubs/vis/).
Provide printed checklist to patient listing vaccines administered.
Record in the clinic record vaccines administered, lot number, and date.
Document vaccines offered to but declined by patient as well as nonrecommended vaccines administered at the patient's request.
PROVIDE MALARIA PREVENTION (IF INDICATED)
Determine whether malaria risk exists for the destination country. If yes:
Does the patient's itinerary within that country put him or her at risk? If yes:
Recommend malaria chemoprophylaxis. Several equally effective drugs of choice may be indicated. Ascertain which is best suited to the individual patient and itinerary.
Educate on personal protection against arthropods.
EDUCATE ON TRAVELER'S DIARRHEA
Recommend food and water precautions.
Educate on use of oral hydration and loperamide and prescribe standby therapy for severe diarrhea with azithromycin or a quinolone.
TEACH ESSENTIAL PREVENTIVE BEHAVIORS
Most travel-related health problems, including vaccine-preventable diseases, can be avoided through simple behaviors initiated by the traveler.
Educate on appropriate strategies in the following categories (some topics are not applicable to all destinations): blood-borne and sexually transmitted diseases, safety and crime avoidance, injury prevention, swimming safety, rabies, skin/wound care, tuberculosis, packing for healthy travel, obtaining health care abroad.
DISCUSS OTHER APPLICABLE HEALTH ISSUES
Advise and prescribe for altitude illness, motion sickness, or jet lag.
Discuss prevention of specific travel-related infections that are of some risk to the traveler and have a possible preventive strategy not included in strategies above.
Discuss any minimal-risk conditions (e.g., hemorrhagic fevers) that are a frequent cause of patient anxiety.
Discuss travel restrictions and advisories; consider additional testing, quarantine, and/or vaccination requirements related to emerging infections.

265 APPROACH TO THE PATIENT BEFORE AND AFTER TRAVEL

LIN H. CHEN

Prevention strategies and medical interventions for travelers should be individualized according to a risk assessment that considers both the itinerary and factors that are dependent on the prospective traveler. A structured approach to patient interaction (Table 265-1) is the most efficient way to cover the necessary educational and preventive interventions. Providing clearly printed instructions in lay language is advised. The worldwide epidemiology of travel-related diseases is constantly changing. Special needs travelers, such as individuals who are immunocompromised, pregnant, or have significant underlying disease, should be referred to a specialized travel medicine clinic.

Globally, approximately 100 million people travel from industrialized to developing countries each year, with risks of travel-related illness determined by the route and destination. Depending on the destination, about 20 to 70% of travelers report some illness, mostly mild, self-limited conditions such as diarrhea, respiratory infections, and skin disorders. Infectious diseases account for up to 10% of the morbidity during travel but only 1% of the deaths, with malaria (Chapter 316) being the most common cause.

IMMUNIZATION

The choice of vaccines for an individual traveler is based on the risk of exposure to vaccine-preventable diseases on the planned itinerary, the severity of a disease if it is acquired, and any risks presented by the vaccine itself. Travelers differ in their tolerance of risk. For vaccine-preventable diseases, the monthly incidence for nonimmune travelers to developing countries is most significant for influenza (about 1%; Chapter 332) and for symptomatic hepatitis A (about 0.03%; Chapter 134), but the risk of symptomatic hepatitis B (Chapter 134) is most significant for long-stay travelers (e.g., missionaries) at 0.25% per month. Enteric fever (typhoid and paratyphoid) has a risk of 0.03% per month on the Indian subcontinent and is 10 times lower in Africa and parts of Southeast Asia and Latin America. The risk of contact with animals that could have rabies (Chapter 383) is also substantial, at about 1% per month. The risk of yellow fever (Chapter 351) may be as high as 0.1% per month of travel to an area with current epidemic transmission, but the risk varies greatly among destinations encompassed by the endemic area map. The risk of meningococcal meningitis (Chapter 274), cholera (Chapter 278), polio (Chapter 349), varicella (Chapter 346), and Japanese encephalitis (Chapter 352) in travelers is not known but is thought to be small (<0.0001%). Worldwide measles outbreaks and declining vaccination rates have led to a rise in travel-related

Infectious diseases account for up to 10% of the morbidity during travel but only 1% of the deaths, with malaria (Chapter 316) being the most common cause.

IMMUNIZATION

The choice of vaccines for an individual traveler is based on the risk of exposure to vaccine-preventable diseases on the planned itinerary, the severity of a disease if it is acquired, and any risks presented by the vaccine itself. Travelers differ in their tolerance of risk. For vaccine-preventable diseases, the monthly incidence for nonimmune travelers to developing countries is most significant for influenza (about 1%; Chapter 332) and for symptomatic hepatitis A (about 0.03%; Chapter 134), but the risk of symptomatic hepatitis B (Chapter 134) is most significant for long-stay travelers (e.g., missionaries) at 0.25% per month. Enteric fever (typhoid and paratyphoid) has a risk of 0.03% per month on the Indian subcontinent and is 10 times lower in Africa and parts of Southeast Asia and Latin America. The risk of contact with animals that could have rabies (Chapter 383) is also substantial, at about 1% per month. The risk of yellow fever (Chapter 351) may be as high as 0.1% per month of travel to an area with current epidemic transmission, but the risk varies greatly among destinations encompassed by the endemic area map. The risk of meningococcal meningitis (Chapter 274), cholera (Chapter 278), polio (Chapter 349), varicella (Chapter 346), and Japanese encephalitis (Chapter 352) in travelers is not known but is thought to be small (<0.0001%). Worldwide measles outbreaks and declining vaccination rates have led to a rise in travel-related

ABSTRACT

The worldwide epidemiology of travel-related diseases is constantly changing, and emerging pathogens such as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) can impose abrupt and drastic challenges in our understanding of travel-related health problems. Prevention strategies and medical interventions must be individualized according to a risk assessment that considers individual health status, the itinerary, the anticipated activities, and other factors that are dependent on the prospective traveler. A structured approach to patient interaction is the most efficient way to cover the necessary educational and preventive interventions. Because many of the measures and advice will be initiated only much later at the traveler's destination, clearly printed instructions in lay language are advisable. Special needs travelers, such as those who are immunocompromised, pregnant, or have significant underlying disease, should be referred to a specialized travel medicine clinic.

measles (Chapter 338). The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2; Chapters 335-337) pandemic created additional risks despite associated travel restrictions.

A number of vaccines (Table 265-2; see also Chapter 15) are available for prospective travelers and can be administered in the travel medicine setting when indicated.

VERIFICATION AND UPDATE OF ROUTINE IMMUNIZATIONS

Because of the increased prevalence of many infections worldwide, routine adult immunizations (Chapter 15) must be current.[1] If no adult doses of tetanus/diphtheria/acellular pertussis (Tdap) have ever been given, a dose of Tdap should be given regardless of the time elapsed since the last tetanus/diphtheria vaccination. Persons born in the United States before 1957 or born anytime in the developing world are considered immune to measles. Other adult travelers should have received at least two doses of live measles–containing vaccine during their life unless a history of measles infection can be documented. Unvaccinated persons who meet the accepted routine indications for influenza or pneumococcal vaccines (Chapter 15) should receive these vaccines during the pretravel consultation. Two doses of varicella vaccine spaced by at least 4 weeks should be considered for adult travelers without evidence of varicella immunity, but adults born before 1980 in the United States are considered immune.

VACCINES TO CONSIDER FOR ALL DEVELOPING WORLD TRAVELERS

A number of additional vaccines should be administered depending on the travel destinations.[2]

Hepatitis A

Vaccination against hepatitis A (Chapter 134) is indicated for every nonimmune traveler to countries or areas with moderate to high risk of infection, which includes essentially any country other than the United States, Canada, Japan, Australia, New Zealand, Scandinavian countries, and developed countries in Europe. Because outbreaks also occur in developed countries, the vaccine is beneficial for all persons and has been incorporated into the routine childhood immunization schedule in the United States. A single dose of hepatitis A vaccine given any time before travel provides adequate protection. Persons with a history of hepatitis or who previously lived in an endemic country for a prolonged period may benefit from prevaccination serum antibody testing.

Hepatitis B

Pretravel hepatitis B vaccination (Chapter 134) is indicated for all nonvaccinated travelers with standard indications, such as health care providers, and all longer-stay travelers who will be visiting or residing in high- or moderate-risk areas. Transmission by routes such as sexual contact, blood transfusions, contaminated medical equipment, body piercing, tattooing, acupuncture, and sharing of bathroom facilities is difficult to control or to predict in the context of travel. Vaccination is advocated for some short-term travelers, especially younger travelers and travelers who anticipate being in close contact with local populations, even if they have no specific risk factors. Adventure travelers (accident prone), backpackers, and travelers with underlying medical conditions are more likely to require contact with the medical system. Accelerated and hyperaccelerated schedules (see Table 265-2), which are used widely in practice and are approved in many countries, are helpful in administering all

TABLE 265-2 TRAVEL-RELATED VACCINES OF ADULTS

DISEASE	VACCINE	PRIMARY COURSE (A: ACCELERATED SCHEDULE)	ROUTE	FURTHER BOOSTERS
VACCINES TO CONSIDER FOR ALL DEVELOPING WORLD TRAVELERS				
Hepatitis A	Killed virus	0, 6-18 months	IM	None
Hepatitis B	Recombinant viral antigen	0, 1, 6 months	IM	None
		A: 0, 1, 2 months and 12 months	IM	
		A: 0, 1, 3 weeks and 12 months*	IM	
	Recombinant, adjuvanted	0, 1 month	IM	None
Hepatitis A/B	Combination of monovalent preparations	0, 1, 6 months	IM	None
		A: 0, 1, 3 weeks and 12 months	IM	
Typhoid	Capsular Vi polysaccharide	Single dose	IM	2 years
	Live attenuated Ty21a bacteria	0, 2, 4, 6 days	Oral	5 years
Influenza	Inactivated viral	Single dose	IM	Annual
	Live attenuated virus	Single dose (<50 years of age only)	Nasal	Annual
Varicella	Live attenuated virus	0, 4-8 weeks	SQ	None
VACCINES FOR CERTAIN DESTINATIONS				
Yellow fever	Live attenuated 17D virus	Single dose	SQ	10 years for special-risk persons; the majority of travelers are considered to have lifelong protection from one dose
Meningococcus	Quadrivalent conjugated polysaccharide (A, C, Y, W135)	Single dose	IM	5 years
Rabies	Inactivated viral cell culture	0, 7, 21-28 days	IM†	None routinely but two doses after each exposure
		0, 7 days per WHO‡		
Japanese encephalitis (Vero cell)	Inactivated viral	0, 28 days	IM	1 year if at continued risk; no data on subsequent doses
		A: 0, 7 days	IM	
Polio§	Inactivated viral	Single dose if adequate childhood series	SQ; IM acceptable	None
Cholera	Live attenuated bacteria (CVD 103-HgR)	Single dose	Oral	3 months
	Killed bacteria + recombinant B toxin subunit	0, 1 week	Oral	2 years for cholera; 3 months for ETEC

*Regimen not approved by the U.S. Food and Drug Administration for monovalent hepatitis B vaccine but approved for combination hepatitis A/B vaccine containing the same quantity of hepatitis B antigen.
‡In the United States, the Advisory Committee on Immunization Practices considers a two-dose pre-exposure regimen to provide boostability up to 3 years, and a third dose administered from day 21 up to 3 years provides long-term boostability. An alternate option is to check the rabies antibody titer at 1 to 3 years after the 2-dose series. Long-term boostability is established if the titer is high.
†Intradermal rabies preexposure vaccine is no longer produced, and the intramuscular 1.0-mL vials are not licensed for intradermal use in a 0.1-mL dose.
§Oral polio vaccine is no longer produced or used.
A = accelerated regimen to be used for imminent departures; ETEC = enterotoxigenic *E. coli*; IM = intramuscular; SQ = subcutaneous.

three primary doses necessary for high assurance of protection in the frequent circumstance in which the traveler is leaving in a very short time and is at risk of exposure to hepatitis B. An adjuvanted two-dose hepatitis B vaccine with a 1-month interval produces excellent rapid response.

Combination Hepatitis A and Hepatitis B Vaccine

The combined hepatitis A and hepatitis B vaccine provides convenience for travelers who have indications for both vaccines. An accelerated 3-week schedule (see Table 265-2) is approved by the U.S. Food and Drug Administration.

Typhoid

Vaccination against typhoid (Chapter 284) is indicated for all travelers to the Indian subcontinent and should be considered for individuals who are traveling to other endemic areas under all but the most deluxe and protected of conditions. The risk increases with duration of the trip, lodging and eating with local residents, and extent of travel beyond the usual tourist itineraries. Current typhoid vaccines do not protect against *Salmonella paratyphi*, which is emerging in many areas.[3] Adherence to the oral vaccine regimen may be as low as 70%.

Influenza

Influenza (Chapter 332) is transmitted year-round in the tropics and is the most common vaccine-preventable illness in travelers. An increased risk of influenza also is reported among cruise ship passengers. All travelers to the tropics or to destinations where influenza virus is currently circulating should strongly consider influenza vaccination,[4] even if they are not otherwise at high risk.

VACCINES FOR CERTAIN DESTINATIONS

Yellow Fever

The primary indication for vaccination against yellow fever (Chapter 351) is to prevent infection in individuals who are traveling to high-risk areas (see www.cdc.gov/travel), but a number of African countries and one in South America (French Guiana) require proof of yellow fever vaccination from all arriving travelers. Country-specific yellow fever entry requirements can be found at www.who.int/ith/chapters/en/index.html. In general, all healthy adult travelers to areas with a risk of yellow fever transmission should be vaccinated. Neither yellow fever vaccine nor any other vaccine is currently required for readmission to the United States. The true duration of immunity from yellow fever vaccination appears to be much longer than 10 years and may exceed 30 years.

Meningococcus

Vaccination against meningococcal infection (Chapter 274)[5] is recommended for travelers to Africa's sub-Saharan "meningitis belt" during the dry season from December through June, especially if prolonged contact with the local populace is likely. Out-of-season epidemics also have occurred in Ethiopia, Somalia, and Tanzania. Muslims undertaking Hajj and Umrah pilgrimages in Saudi Arabia are at a higher risk of meningococcal disease (Chapter 274), and proof of vaccination with the quadrivalent vaccine within the past 3 years (for polysaccharide vaccine) or 5 years (for conjugate vaccine) is required to obtain pilgrimage visas. Polysaccharide vaccine is no longer produced in Western countries.

Rabies

A preexposure vaccination series against rabies (Chapter 383) is indicated for long-stay travel to endemic areas of Latin America, Asia, or Africa, where the rabies threat is constant and where access to adequate postexposure rabies immune globulin and vaccine is likely to be limited. For short-term travel, risk groups for whom immunization should be considered include adventure travelers, bikers, hikers, cave explorers, and business travelers who travel for short but frequent trips and plan to go running outdoors on these trips. The World Health Organization (WHO) endorses a two-dose schedule for preexposure prophylaxis. The Advisory Committee on Immunization Practices considers a two-dose pre-exposure regimen to provide boostability up to 3 years. To assure long-term boostability, a third dose should be administered from day 21 up to 3 years or the rabies antibody level can be checked at 1 to 3 years following the two-dose series.

Japanese Encephalitis

Japanese encephalitis (Chapter 352) is endemic to many rural farming areas of Southeast Asia and the Indian subcontinent, and sporadic cases with severe sequelae continue to occur in travelers.[6] In temperate regions, the transmission season is from May through October. In tropical or subtropical regions of Oceania and Southeast Asia, transmission may occur year-round. Vaccination is recommended for long-stay travel to an endemic rural area; expatriation to anywhere in an endemic country; short-term travel to endemic rural areas with extensive outdoor exposure, such as with adventure travel; and short-term travel in the face of a current local epidemic.

Polio

Because of eradication efforts, poliomyelitis (Chapter 349) remains in only a few countries, but complete control remains elusive. Adults who are traveling to countries where polio remains endemic or where outbreaks are occurring (updated information at www.polioeradication.org) and who have previously completed a primary vaccine series should receive a one-time, single-dose booster of inactivated polio vaccine.

Cholera

Vaccination against cholera (Chapter 278) is no longer required by any country, and the risk to typical travelers is insignificant.[7] However, medical and aid workers who are staying for short periods in disaster areas or refugee camps may consider cholera vaccine. An oral live attenuated bacterial vaccine is available in the United States, and an oral killed whole cell–B subunit vaccine is available widely outside the United States.

SEQUENCE OF TRAVEL-RELATED VACCINES

All currently indicated immunizations can and should be given at the same time and in any combination (Chapter 15), including vaccination against SARS-CoV-2. If two live viral antigens are not administered on the same day, they must be spaced by a month. Minimum intervals between vaccine doses must be respected, although 4 days or fewer before the next interval are acceptable. Regimens that involve 1-week intervals (rabies, Japanese encephalitis, accelerated hepatitis) are exceptions. There is not a maximum interval between doses of a primary vaccine series; interrupted series (except oral typhoid and rabies) need not be restarted but can be resumed beginning with the dose that is overdue.

MALARIA CHEMOPROPHYLAXIS

An average of 1500 imported cases of malaria (Chapter 316) are reported annually in the United States. Estimates of risk in travelers not taking chemoprophylaxis vary widely by destination but range from 3.4% per month in West Africa to one tenth that on the Indian subcontinent and a further 10-fold reduction in South America. The majority of cases of imported malaria in the United States and Europe occur in immigrants visiting friends and relatives abroad.

In the limited number of countries where it is still effective (e.g., mainly the Caribbean and countries west of the Panama Canal), chloroquine 500 mg salt (300 mg base) per week, beginning the week before the first exposure to malaria and continuing for 4 weeks after the last exposure, is still the drug of choice. However, atovaquone/proguanil (250/100 mg) may still be used by short-stay travelers who prefer the shorter duration of that regimen.

For all other areas of the world, four regimens are equally effective, and the choice depends on both traveler and itinerary factors. Atovaquone/proguanil (250/100 mg) is a well-tolerated, once-a-day drug that should be started 1 day before arrival in the malarious area and continued for 7 days after the last exposure. The short period of postexposure use makes it convenient for the many travelers on typical 1- to 3-week itineraries. The medications' cost and need for daily dosing make it difficult to use for extended periods. Weekly mefloquine (250 mg) is given 2 and preferably 3 weeks before the first exposure to malaria and continued for 4 weeks thereafter. Weekly dosing and a long track record of efficacy make this drug the most effective for long-stay travelers. If long-stay travelers have contraindications to mefloquine, daily doxycycline (100 mg) beginning 1 day before exposure can be used; unlike atovaquone/proguanil, it must be continued for 4 weeks after exposure. Approximately 5% of individuals who take either mefloquine or doxycycline discontinue therapy because of side effects. One advantage of doxycycline prophylaxis is that it also seems to reduce the risk of influenza-like illness.[8] Tafenoquine, licensed by the U.S. Food and Drug Administration (FDA) in 2018, can be used for chemoprophylaxis only after confirmation of an adequate G6PD enzyme level. The dosing is 200 mg daily for 3 days prior to arrival in the malarious area, continued weekly during exposure, and 1 week after the last exposure. Chemoprophylaxis may be started well before departure (3 to 4 weeks for mefloquine) in individuals who are concerned about possible intolerance

that would interfere with taking prophylaxis while abroad in locations where alternative regimens could not be obtained.

Travelers should be reminded in writing to continue antimalarial drugs for the appropriate period after the last possible exposure, that malaria can still occur despite chemoprophylaxis, and that a malaria smear or malaria rapid diagnostic test is mandatory for any febrile illness occurring within 3 months after travel. Unfortunately, up to one third of travelers may not be fully compliant with their prophylactic regimen.[9] Prevention of malaria in travelers residing in malarious areas for 6 months or more presents a more complex challenge (Chapter 316).

DENGUE, CHIKUNGUNYA, ZIKA

An estimated 100 million cases of dengue fever (Chapter 352) and 250,000 cases of dengue hemorrhagic fever occur annually (Chapter 351).[10] Dengue accounts for up to 2% of all illness in returned travelers, and dengue is the most common systemic febrile illness in returned travelers from every region except sub-Saharan Africa,[11] where malaria still predominates.

Chikungunya virus infection and Zika virus (Chapter 352) were first noted in Africa but have disseminated widely in the tropics, the Pacific Islands, and the Americas. Patients typically have self-resolving fever, mild constitutional symptoms, and sometimes arthralgias. Zika infection can cause severe abnormalities to a fetus and is also associated with a postinfection Guillain-Barré syndrome (Chapter 388) that may not manifest until after the traveler has returned home.[12]

Dengue fever, chikungunya infection,[13] and Zika virus infection are transmitted by day-biting *Aedes* mosquitoes, thereby reinforcing the need to instruct travelers to the tropics in the need for both day and night use of repellents. Several candidate vaccines are in development.

TRAVELER'S DIARRHEA

The most frequent cause of traveler's diarrhea is enterotoxigenic *Escherichia coli* (Chapter 280), and in some locations enteroaggregative *E. coli*. *Salmonella* (Chapter 284), *Shigella* (Chapter 285), and *Campylobacter* (Chapter 279) each account for about 5 to 15% (Table 265-3).[14,15] In Asia, noncholera vibrios are significant. Protozoa account for less than 5%. In adults, norovirus and rotavirus (Chapter 350) are increasingly detected. The mean duration of traveler's diarrhea, even if it is untreated, is only 4 days.

All travelers to the developing world should be thoroughly educated in self-therapy for diarrheal disease and carry the appropriate agents while traveling (Table 265-4). The majority of patients respond to loperamide. However, patients who have fever, systemic symptoms, bloody diarrhea, or diarrhea that is severe or unresponsive benefit from self-treatment with azithromycin. A single dose of 1000 mg is usually sufficient, but patients may continue 500 mg orally daily for up to 3 days if the diarrhea persists. Because of a significant prevalence of quinolone-resistant enteropathogens, particularly *Campylobacter* and *Salmonella*, ciprofloxacin (500 mg/day orally for 3 days) is a less attractive alternative. Other alternatives include oral single-dose levofloxacin (750 mg) or a 3-day course of rifaximin (200 mg 3 times daily).[A1] One of the more commonly identified nonbacterial causes of traveler's diarrhea is giardiasis, which is often refractory to standard treatment with metronidazole or tinidazole; additional therapy may be needed with antiparasitic combinations or with quinacrine (Chapter 322).[16]

For prevention of traveler's diarrhea, bismuth subsalicylate may be used. Most guidelines do not recommend antibiotic prophylaxis for the typical traveler because of potential adverse drug effects while away from medical care and because effective rapid-onset therapy is available for diarrhea should it occur. Exceptions include travelers with advanced human immunodeficiency virus (HIV) infection, individuals who have an underlying chronic medical problem that makes them more prone to adverse consequences from diarrhea, and travelers on a vital mission for a short period (less than 1 week) who cannot tolerate even a day of disability. If indicated, antibiotic prophylaxis can be carried out with rifaximin (200 mg) orally twice per day,[A2] but such prophylaxis should be used only for trips of 2 weeks or less.

SARS-COV-2

SARS-CoV-2 (Chapters 335-337) has reinforced the potential of travel to introduce and spread emerging infections worldwide. The transmission is predominantly person-to-person via droplets and aerosols, and vaccination provides robust protection against severe disease, hospitalization, and death despite breakthrough infections. All travelers should be fully vaccinated against SARS-CoV-2 but also should still take precautions during travel: avoid crowds especially indoors; avoid poorly ventilated spaces; maintain physical distance from others; wear masks in public indoor spaces, crowded outdoor spaces, and public transportation; wash hands well; and clean contaminated surfaces.

PREVENTIVE BEHAVIORS

Most travel-related health problems, including many infectious diseases, can be significantly reduced by appropriate behaviors during travel.

TABLE 265-4 TREATMENTS FOR TRAVELER'S DIARRHEA

PHARMACOLOGIC AGENT	RECOMMENDED DOSAGE	EFFECTIVENESS AND ADVERSE EVENTS
Bismuth subsalicylate	525 mg (1 oz liquid or 2 tablets chewed well) as needed up to 16 tablets in 24 hours	Moderately effective, turns stool and tongue black, may cause tinnitus from systemic salicylate absorption
Loperamide	4 mg then 2 mg orally after each unformed stool up to 8 mg/day	Rapid relief of diarrhea but must be combined with an antibiotic in patients with fever or dysentery
Azithromycin	500 mg orally daily for 3 days or single dose of 1000 mg	First choice for all severe diarrhea but nausea is frequent
Ciprofloxacin	500 mg or 750 mg orally daily for 1-3 days	Fluoroquinolones may be used for nonsevere diarrhea except for India and Southeast Asia where fluoroquinolone-resistant *Campylobacter* is common
Rifaximin	200 mg orally tid for 3 days	Ineffective against invasive pathogens (e.g., *Shigella, Salmonella, Campylobacter*)

MOSQUITO PROTECTION

Protection against arthropods will help prevent malaria (Chapter 316), dengue (Chapter 352), leishmaniasis (Chapter 319), filariasis (Chapter 327), and a number of important arboviral diseases (Chapters 351 and 352). Travelers should be instructed to clothe themselves to reduce exposed skin as much as practicable and to apply a repellent containing active ingredients (e.g., DEET 30 to 35%, picaridin, oil of lemon eucalyptus, IR3535, or 2-undecanone) to all exposed, nonsensitive areas of the body every 4 to 6 hours. More frequent application is required for agents containing lower concentrations of DEET. Travelers should sleep under a permethrin-impregnated bed net in malarious areas[A3] unless they are in a sealed air-conditioned environment. Although anopheline mosquitoes bite at night, *Aedes* spp mosquitoes usually bite during the day, so vigilance at all times of day is necessary.

FOOD AND WATER PRECAUTIONS

Travelers to developing countries should be diligent in washing their hands frequently; avoiding food from dubious eating places, markets, and roadside vendors; avoiding buffets where there are no food covers or fly controls; avoiding high-risk foods such as shellfish, reef fish (ciguatera risk; Chapter 98), undercooked meats and poultry, dairy products, unpeeled fruits, cold sauces, and salads; avoiding both tap water and drinks or ice made from tap water; and using sealed bottled water or chemically treated, filtered, or boiled water to drink and brush their teeth.

SEX

Education on the incidence of HIV infection (Chapter 353) and sexually transmitted infections among professional sex workers abroad, on the use of condoms, and on the failure rate of condoms (3 to 5% breakage/slippage) should be given regardless of the apparent circumstances of the traveler. Unprotected sex, even with fellow travelers, is considered high risk. Travel is a disinhibiting experience in itself, and alcohol consumption tends to increase during travel. HIV pre-exposure prophylaxis (Chapter 356) has become more widely accepted, and daily prophylaxis (200 mg emtricitabine plus 300 mg tenofovir) is an option to prevent HIV infection in persons at risk of exposure through sexual contact, including travelers.

BLOOD-BORNE PATHOGENS

Blood, blood products, syringes, and contaminated medical or dental instruments are a risk after accidents or trauma. Travelers should consider carrying an infusion set, needles, and a suture kit for high-risk areas. If possible, they should defer local medical treatment and instead travel to a facility where safety can be ensured. Tattooing, acupuncture, and body piercing carry similar risks. Health care providers and others at risk in areas of high HIV prevalence without sophisticated medical infrastructure may consider carrying a 1- to 2-week supply of antiretroviral agents to begin immediate postexposure prophylaxis, with the understanding that this initial measure is designed to allow time for travel to an adequate medical facility that is able to provide sophisticated testing and counseling. Two options are (1) emtricitabine 200 mg/tenofovir alafenamide fumarate [TAF] 25 mg 1 tablet daily plus raltegravir 400 mg 1 tablet twice daily (or dolutegravir 50 mg 1 tablet daily) and (2) emtricitabine 200 mg/tenofovir 300 mg 1 tablet daily plus dolutegravir 50 mg 1 tablet daily.

PROTECTION AGAINST SKIN DISEASES

Infected mosquito bites are common. All travelers should practice good hand hygiene in dirty environments and cover open wounds. Scabies and lice infestations (Chapter 98) can be prevented by good personal hygiene. In Africa, all clothes dried outdoors should be ironed to avoid cutaneous myiasis (Chapter 98) caused by the tumbu fly. Hats and sunscreen are mandatory in the tropics. Sunscreen should always be applied to skin before, and not after, an application of DEET.

SWIMMING AND WATER EXPOSURE

Travelers should be instructed to avoid recreational (swimming, rafting, wading) or other exposure to fresh water in areas that are endemic for schistosomiasis (Chapter 326). Hikers, bikers, and adventure travelers should consider prophylaxis with 200 mg of doxycycline orally once per week because of the significant risk of leptospirosis (Chapter 298) that exists in fresh water throughout the developing world. Walking barefoot in tropical areas predisposes to hookworm (Chapter 327), *Strongyloides* infection (Chapter 327), and cutaneous larva migrans (Chapter 327).

PREVENTION OF RESPIRATORY INFECTIONS

A predeparture baseline tuberculin skin or blood test with annual retesting is indicated for long-stay travelers to developing countries. Individuals whose skin or blood tests convert to positive require appropriate treatment to prevent active tuberculosis (Chapter 299). To reduce risk of exposure to respiratory pathogens such as tuberculosis and SARS-CoV-2, travelers should avoid crowded public transportation or crowded public places, follow health authority guidance on masking, and distance themselves immediately from anyone with a chronic or heavy cough. Expatriates should screen domestic help for tuberculosis.

NONINFECTIOUS TRAVEL PROBLEMS

TRAVELER'S THROMBOSIS AND JET LAG

Travel-related immobility is associated with deep venous thrombosis and pulmonary embolism (Chapter 68) in otherwise healthy travelers, but individuals with known risk factors are at highest risk. All travelers should avoid dehydration, avoid alcohol, and exercise their legs regularly in flight. Fortunately, the risk of pulmonary embolus is very low on flights less than 6 hours. Of many recommendations for prevention, only the use of graded 15 to 30 mm Hg compression stockings for individuals at higher risk is supported by randomized trials,[A4] although prophylactic antithrombotic agents such as low-molecular-weight heparin (e.g., enoxaparin 40 mg subcutaneously 2 to 4 hours preflight) or a direct-acting oral anticoagulant (e.g., rivaroxaban 10 mg orally) are sometimes used in practice in patients with a history of thrombosis or a high risk for developing it (e.g., patients with heart failure).[17] Aspirin therapy is of no proven benefit in this setting.

Jet lag (Chapter 374) occurs after crossing three or more time zones. Melatonin (as little as 0.5 mg 30 minutes orally prior to targeted bedtime) may be helpful for reducing the severity of jet lag,[18] and zolpidem (5 mg) taken orally for a few nights at bedtime at the destination is generally effective.

ALTITUDE ILLNESS

Whether ascending by foot, car, or airplane, acute mountain sickness occurs in at least 25% of people who ascend rapidly to 2500 m or more and in most people who go quickly to 3000 m or more (Chapter 82). High altitude can also exacerbate cardiac and pulmonary conditions.[19] Gradual ascent over several days is rarely practiced by modern travelers. For prevention of altitude illness, acetazolamide 125 mg orally twice a day, beginning the morning of the day before ascent and continuing through the day after ascent, is effective.[A5] If symptoms of mountain sickness, such as nausea, vomiting, anorexia, lightheadedness, fatigue, or insomnia, persist beyond the day after ascent, travelers may continue to take one tablet orally each evening. Other medications such as dexamethasone (4 mg orally twice daily) also can be used for prophylaxis or treatment (Chapter 82).[A6] Severe complications, such as pulmonary or cerebral edema, are uncommon under 3500 m and are best treated by oxygen and immediate descent. Those traveling above 3500 m for longer than a brief transit of a few hours should consult an expert.

POST-TRAVEL CARE

The approach to the post-travel patient requires knowledge of world geography, the epidemiology of disease patterns in 230 or so countries, and the clinical presentation of a wide spectrum of disorders.[20] Most illnesses are mild and self-limited, and many are noninfectious. Based on 43,000 ill-returned travelers seen by the GeoSentinel Surveillance Network, specific travel destinations are associated with the probability of the diagnosis of certain diseases (E-Table 265-1). Diagnostic approaches and empirical therapies can be guided by these destination-specific data. Important region-specific disease occurrence data (Table 265-5) indicate that (1) febrile illness[21,22] is most important after travel to Africa and Southeast Asia; (2) malaria is one of the top three diagnoses from every region, but dengue is the most common febrile illness from every region outside of sub-Saharan Africa[23]; (3) in sub-Saharan Africa, rickettsial disease is second only to malaria as a cause of fever; (4) respiratory disease is most important in Southeast Asia and sub-Saharan Africa; and (5) acute diarrhea is disproportionately from South Central Asia. Causes of post-travel fever also depend on the incubation period for various infections (Table 265-6).

Fever alone raises the possibility of malaria (Chapter 316) and should prompt a rapid diagnostic nucleic acid test so that antimalarial or other definitive treatment can be initiated rapidly if it is indicated. Dengue virus infection (Chapter 352) usually has a 2- to 7-day incubation period, but it can be up to 14 days. High fever is usually accompanied by severe headache, myalgia, and arthralgia. Within 5 days of the onset of fever, a diffuse maculopapular rash commonly appears. Diagnosis is by PCR, antigen testing, or IgM serology testing. Chikungunya virus (Chapter 352) infection has a similar clinical presentation to dengue virus

E-TABLE 265-1 SOME KEY DISEASES REPORTED IN FIVE OR MORE TRAVELERS AMONG >43,000 REPORTED ILLNESSES

DIAGNOSES	# OF CASES	TRAVEL HISTORY
GASTROINTESTINAL		
Giardia	1426	India, Thailand, Nepal, and Ghana
Campylobacter	753	India, Thailand, Indonesia, and Tanzania
Strongyloides	483	India, Vietnam, Ghana, and Dominican Republic
Salmonella enteritis	367	Thailand, India, Indonesia, and Egypt
Shigella	271	India, Egypt, Ghana, and Indonesia
Entamoeba histolytica	340	India, Indonesia, Mexico, and Thailand
Vibrio	9	5 cases in Latin America (2 cases acquired in Mexico), 3 in Asia, 1 in sub-Saharan Africa
FEBRILE		
Plasmodium falciparum	1990	Ghana, Comoros, Nigeria, and Côte d'Ivoire
Plasmodium vivax	480	India, French Guyana, Myanmar, and Papua New Guinea
Dengue	1473	Thailand, Indonesia, India, and Brazil
Enteric fever	467	India, Nepal, Pakistan, and Bangladesh
Spotted fever rickettsia	267	South Africa (68.9%), Zimbabwe, Tanzania, and Swaziland
Chikungunya	164	India, Malaysia, Indonesia, and Thailand
Hepatitis A	120	India, Morocco, Egypt, and Mexico
Acute HIV	84	Thailand, Brazil, Guinea, and Germany
Leptospirosis	83	Thailand, Laos, and Costa Rica
Hepatitis E	45	India (40%), Pakistan, and Bangladesh
Brucellosis, acute	33	India, Sudan, and Iraq
Measles	33	India, Thailand, and France
Histoplasmosis	23	Guatemala and Costa Rica
Rickettsia typhi (flea-borne)	17	Cambodia, Malaysia, Vietnam, Indonesia, and Nepal
Visceral leishmaniasis	16	India, Greece, Portugal, and Spain
Orientia tsutsugamushi (scrub typhus)	14	Thailand and Vietnam
Rubella	11	Vietnam and Thailand
Melioidosis	9	Thailand, Singapore, and Malaysia
Mumps	8	Different country for each case (2 in Western Europe, 4 in sub-Saharan Africa, 1 in Latin America, and 1 in Asia)
African trypanosomiasis	6	Zambia (3 cases), Tanzania, Zimbabwe, and Burkina Faso
Relapsing fever	6	Senegal, South Africa, and Morocco
Ross River virus	5	Australia
DERMATOLOGIC		
Rabies prophylaxis after bite or scratch	1249	Thailand, Indonesia, China, and India
Cutaneous larva migrans	806	Thailand, Brazil, Mexico, and Malaysia
Leishmaniasis (cutaneous or mucocutaneous)	264	Bolivia, Afghanistan, and Costa Rica
Myiasis	174	Senegal, Brazil, Costa Rica, and Belize
Tungiasis	87	Brazil, Madagascar, Uganda, and Ethiopia
Gnathostomiasis	12	Cambodia and Indonesia (92% from Asia)
Leprosy	11	Pakistan and Vietnam
Cutaneous atypical mycobacteria	6	All different (Caribbean, sub-Saharan Africa, and South-Central Asia)
RESPIRATORY OR PHARYNGEAL		
Influenza	367	
H1N1	176	United States, Australia, United Kingdom, and Philippines
Influenza A or B	191	Indonesia, Thailand, India, and China
Tuberculosis	170	
MDR or XDR pulmonary tuberculosis	3	1 case each for Nigeria and India (1 case unknown)
Legionellosis	35	China, Italy, and Spain
Pulmonary atypical mycobacteria	35	China, Thailand, Kenya, South Africa, and North America
Pertussis	30	India and China
NEUROLOGIC		
Ciguatera intoxication	51	Bahamas and Dominican Republic
Neurocysticercosis	21	India
Tuberculosis meningitis or tuberculoma	13	India and Pakistan

E-TABLE 265-1 SOME KEY DISEASES REPORTED IN FIVE OR MORE TRAVELERS AMONG >43,000 REPORTED ILLNESSES—cont'd

DIAGNOSES	# OF CASES	TRAVEL HISTORY
Scombroid, neurotoxic or paralytic shellfish poisoning	7	Mauritius (2 cases) and other (2 cases in Western Europe and 2 cases in Southeast Asia)
West Nile virus	5	1 case each in Afghanistan, Costa Rica, Greece, and Israel (1 unknown)
OTHER		
Schistosomiasis	792	Malawi, Uganda, Tanzania, and Ghana
Filariasis	113	Cameroon, Gabon, Democratic Republic of Congo, and Central African Republic
Lyme disease	77	United States, Germany, and Italy
Visceral larva migrans	16	6 cases in Southeast Asia (2 cases acquired in Thailand), 5 in Latin America and the Caribbean, 3 in sub-Saharan Africa, and 2 cases unknown
Fasciola	14	Australia, Germany, France, and the Netherlands
Clonorchis	12	Thailand, Laos, and China
Trichinellosis	12	Poland and Serbia

HIV = human immunodeficiency virus; MDR = multidrug-resistant; XDR = extensively drug-resistant.

TABLE 265-5 CAUSES OF FEVER ASSOCIATED WITH TRAVEL TO DIFFERENT GEOGRAPHIC AREAS

DESTINATION	COMMON CAUSES OF FEVER	OTHER POSSIBLE CAUSES OF FEVER	RARE BUT NOTABLE
Caribbean	Chikungunya virus, dengue virus, malaria, Zika virus	Histoplasmosis, leptospirosis	
Central America	Chikungunya virus, dengue virus, malaria, Zika virus, enteric fever	Leptospirosis, histoplasmosis, coccidioidomycosis, leishmaniasis, paracoccidioidomycosis, brucellosis	*T. cruzi*, hantavirus
South America	Chikungunya virus, dengue virus, malaria, Zika virus	Bartonellosis, leptospirosis, enteric fever, histoplasmosis, paracoccidioidomycosis, brucellosis	*T. cruzi*, hantavirus, yellow fever
South-Central Asia	Dengue virus, enteric fever, malaria	Chikungunya virus, *C. burnetii*, leishmaniasis (visceral), scrub typhus and other Rickettsiae	Crimean-Congo, Japanese encephalitis, Nipah virus
Southeast Asia	Dengue virus, malaria, chikungunya virus, Zika virus, enteric fever	Leptospirosis, melioidosis	Hantavirus, Japanese encephalitis, Nipah virus, paragonimiasis, scrub typhus, talaromycosis
Sub-Saharan Africa	Malaria, Rickettsiae, acute schistosomiasis (Katayama fever), dengue virus, acute HIV	African trypanosomiasis, amebic liver abscess, brucellosis, Chikungunya virus, enteric fever, *N. meningitidis* meningitis	Histoplasmosis, leishmaniasis (visceral), other arboviruses (Rift valley, West Nile, yellow fever), viral hemorrhagic fevers (Ebola, Lassa, Marburg, Crimean-Congo)

Adapted from https://wwwnc.cdc.gov/travel/yellowbook/2020/posttravel-evaluation/fever and Marks M, Johnston V, Brown M. Fever in the returned traveler. HIV = human immunodeficiency virus.

TABLE 265-6 DIFFERENTIAL DIAGNOSIS FOR FEVER IN THE RETURNING TRAVELER BASED UPON INCUBATION PERIOD

SHORT (<10 DAYS)	MEDIUM (10-21 DAYS)	LONG (>21 DAYS)
Malaria	Malaria	Malaria
Arboviruses (including Dengue, Chikungunya, Zika)	Enteric fever (*Salmonella typhi* and *Salmonella paratyphi*)	Schistosomiasis (acute)
Hemorrhagic fever viruses (including Ebola, Crimean-Congo, Lassa)	Acute HIV infection	*M. tuberculosis*
Enteric fever (*Salmonella typhi* and *Salmonella paratyphi*)	Hemorrhagic fever viruses (including Ebola, Crimean-Congo, Lassa)	Acute HIV infection
Spotted fever Rickettsiae, *O. tsutsugamushi*	Some Rickettsiae (e.g., epidemic typhus, endemic typhus)	Viral hepatitis
Respiratory viruses	*C. burnetii*	Filariasis
Enteritis (bacterial, viral)	Giardiasis	*C. burnetii*
Bacterial pneumonia	Cytomegalovirus	*T. pallidum*
Relapsing fever	Toxoplasmosis	Epstein-Barr virus (acute)
Amebic dysentery	Amebic dysentery	Amebic liver abscess
N. meningitidis bacteremia	Endemic fungi (including histoplasmosis, coccidioidomycosis)	Leishmaniasis
Meningitis	Brucellosis	Brucellosis
Leptospirosis	Leptospirosis	Bartonellosis (chronic)
Fascioliasis	Babesiosis	Babesiosis
Melioidosis	Rabies	Rabies
Flaviviruses (including tick-borne encephalitis and Japanese encephalitis)	East African trypanosomiasis (acute)	West African trypanosomiasis (chronic)
Brucellosis (rare)	*T. cruzi* (acute)	Cytomegalovirus
Rabies (rare)	Measles	
Trypanosomiasis (rare)	Melioidosis, flaviviruses (including tick-borne encephalitis and Japanese encephalitis) hepatitis A (rare)	

Adapted from Boggild AK, Freedman DO. Infections in returning travelers. In: Bennett JE, Dolin R, Blaser MJ, eds. *Mandell, Douglas, and Bennett's Principles and Practice of Infectious Diseases*. Philadelphia, PA: Elsevier; 2020:3828-3839; and Marks M, Johnston V, Brown M. Fever in the returned traveler. In: Ryan ET, Hill DR, Solomon T, Aronson N, Endy TP, eds. *Hunter's Tropical Medicine and Emerging Infectious Diseases*. Elsevier; 2020:1077-1086. Courtesy of Michael Melia, MD.

except that arthralgia and even arthritis are typical. Zika virus (Chapter 352) infection is usually asymptomatic in adults, but symptomatic persons may have mild nonspecific symptoms similar to chikungunya. Enteric fever (Chapter 284), which exists within the Indian subcontinent and throughout Central and South America, Africa, and other areas of Asia, can cause subacute but progressive fever; it may be diagnosed in blood or stool cultures or by serology but oftentimes requires empiric antibiotics after other causes have been excluded. Viral hemorrhagic fevers (e.g., Ebola, Lassa, and Marburg; Chapter 352), though rare, are also an important consideration because of their infectivity. Fever with dermatologic findings should suggest parasitic infection (e.g., cutaneous larva migrans, leishmaniasis, trypanosomiasis), viral infection (e.g., Zika), rickettsia (e.g., tick bite fever, scrub typhus), or bites (e.g., scabies, myiasis).[24]

Persistent gastrointestinal symptoms in a returning traveler require prompt evaluation and treatment (Table 265-7). Persistent diarrhea is a problem in up to 3% of people who return from developing countries, with parasites (especially *Giardia* [Chapter 322] and *Cryptosporidium* [Chapter 321]) and bacteria (especially enteroaggregative *E. coli* [Chapter 280] and *Shigella* [Chapter 285]) as the leading causes (see Tables 262-1 and 262-2) Diagnosis is based on molecular testing of diarrheal stool (Table 262-4),[25] with supportive care for all, and antibiotics reserved for patients with fever, bloody diarrhea, dehydration, or severe underlying disease (Table 262-5), with the exception that antibiotics should not be used in patients who have Shiga toxin–producing *E. coli*.

Travelers who become ill during or any time up to several months after a foreign trip will frequently associate that illness with a possible travel-specific

TABLE 265-7 COMMON INFECTIOUS AGENTS CAUSING CHRONIC GASTROINTESTINAL DISEASE IN THE RETURNING TRAVELER

	INCUBATION PERIOD (DAYS)	CLINICAL MANIFESTATIONS	DIAGNOSIS	TREATMENT
Giardia	7-10	Abdominal pain, nausea, persistent watery diarrhea	Stool microscopy and stool antigen	Metronidazole, 250 mg, 3 times/day for 7-10 days or 500 mg twice a day for 5-7 days; tinidazole single dose; quinacrine 100 mg 3 times/day for 5 days
Entamoeba histolytica	11-21	Abdominal pain, fever, persistent watery diarrhea	Stool antigen assay	Metronidazole, 500-750 mg, 3 times/day for 7-10 days; plus paromomycin, 500 mg, 3 times/day for 7 days
Strongyloides	11-21	Larva currens, abdominal pain, persistent diarrhea	Stool microscopy	Ivermectin, 200 μg/kg of body weight/day for 2 days
Schistosoma	14-84	Katayama syndrome, abdominal pain, persistent diarrhea, hematuria	Stool and urine microscopy	Praziquantel, 40 mg/kg divided into 2 doses for 1 day for *S. hematobium* and *S. mansoni*, and 60 mg/kg divided into 3 doses for 1 day for *S. japonicum*
Campylobacter	1-4	Acute watery diarrhea, fever	Stool culture	Azithromycin, 500 mg once a day for 3 days
Shigella	1-8	Severe diarrhea, dysentery, fever	Stool culture	Ciprofloxacin, 500 mg twice a day for 3 days
Salmonella				
Serovar Typhi	5-14	Fever, headache, malaise, abdominal pain, diarrhea	Blood and stool culture	Ciprofloxacin, 20 mg/kg/day for 7 days; or azithromycin, 20 mg/kg/day for 7 days
Nontyphoidal	8-24 hours	Fever, headache, malaise, abdominal pain, diarrhea	Blood and stool culture	Ciprofloxacin, 20 mg/kg/day for 7 days; or azithromycin, 20 mg/kg/day for 7 days

Adapted from Ross AG, Olds GR, Cripps AW, et al. Enteropathogens and chronic illness in returning travelers. *N Engl J Med*. 2013;368:1817-1825.

etiology. This association, though sometimes reasonable, is frequently misplaced. Although some travel-related illnesses can be delayed, domestically acquired conditions become increasingly likely as time goes on. Routine causes are common, and common disease are common whether they are acquired during travel or at some time after the trip. Long-term travelers to countries with serious endemic diseases should be evaluated by a travel or tropical medicine specialist when they return to be screened for conditions that may be asymptomatic, such as schistosomiasis or strongyloidiasis.

266 ANTIBACTERIAL CHEMOTHERAPY

ARNOLD LOUIE

Antibiotics provide a backbone for modern interventional medicine, in which surgery, central venous catheters, urinary catheters, implantable devices, and mechanical ventilation have become commonplace. These interventions support seriously ill patients, but they also give bacteria access to normally sterile areas. Therapies for cancer and immune-mediated disease often leave patients severely immunosuppressed. Bacterial infections in such patients are serious, and antibiotics provide critical life-saving support for such patients.

Unfortunately, overuse and poor use of antibiotics have allowed many organisms to develop antibacterial resistance (Chapter 261). Multiresistant *Staphylococcus aureus* has become a plague both in the hospital and in the community. Extended-spectrum β-lactamases and *Klebsiella pneumoniae* carbapenemase enzymes have mediated resistance to many of the most potent and broad-spectrum β-lactam agents, including the carbapenems. Consequently, it is important to understand the principles of antibacterial chemotherapy to obtain the best clinical outcomes for the patient at hand, but also, in a broader sense, to lower the probability of the emergence of resistance so as to maintain the potency of the drugs currently in the therapeutic armamentarium.[1] In this context, the significant decline in the use of antibiotics in the United States in recent years is a good sign.[2]

CHOICE OF ANTIBIOTIC, DOSE, AND ADMINISTRATION SCHEDULE

As in all of clinical medicine, a thorough history and physical examination are central to proper decision making and to achieving optimal therapeutic outcomes in patients with infections. Key to choosing the correct drug, dose, and schedule of antibiotic administration is recognition that an infection exists. The next steps are to document where the infection exists, and then to identify the dominant organisms present at each site of infection. The final step is to determine whether any risk factors might predict the presence of drug-resistant pathogens.

As an example, it is known that community-associated pneumonia (Chapter 85) is caused by certain traditional bacterial pathogens. *Streptococcus pneumoniae* (Chapter 268), *Haemophilus influenzae* (Chapter 277), and *Moraxella catarrhalis* are among the classic bacterial pathogens associated with this entity (Table 266-1). "Atypical" pathogens such as *Legionella* species (Chapter 290), *Mycoplasma pneumoniae* (Chapter 293), and *Chlamydophila pneumoniae* (Chapter 294) also may be seen. In contrast, intra-abdominal infections are dominated by *Escherichia coli* (Chapter 280) and other Enterobacteriaceae (Chapter 281), and anaerobic organisms such as *Bacteroides* species. Consequently, it is important to understand the dominant pathogens present at different infection sites so that the best drug or combination of drugs can be chosen to treat the infection.

Knowing the site of infection is also critical because drugs penetrate differently into different body sites. Classically, penetration is poorer into spaces where there are tight junctions, such as the central nervous system, the eye, and the prostate. In general, the penetration of many classes of antibacterial agents is good into complicated skin and skin structure infection sites. What is often not appreciated is the divergent penetrations of different agents and even agents within the same class into the lung to treat bacterial pneumonia.

266 ANTIBACTERIAL CHEMOTHERAPY

ARNOLD LOUIE

Antibiotics provide a backbone for modern interventional medicine, in which surgery, central venous catheters, urinary catheters, implantable devices, and mechanical ventilation have become commonplace. These interventions support seriously ill patients, but they also give bacteria access to normally sterile areas. Therapies for cancer and immune-mediated disease often leave patients severely immunosuppressed. Bacterial infections in such patients are serious, and antibiotics provide critical life-saving support for such patients.

Unfortunately, overuse and poor use of antibiotics have allowed many organisms to develop antibacterial resistance (Chapter 261). Multiresistant *Staphylococcus aureus* has become a plague both in the hospital and in the community. Extended-spectrum β-lactamases and *Klebsiella pneumoniae* carbapenemase enzymes have mediated resistance to many of the most potent and broad-spectrum β-lactam agents, including the carbapenems. Consequently, it is important to understand the principles of antibacterial chemotherapy to obtain the best clinical outcomes for the patient at hand, but also, in a broader sense, to lower the probability of the emergence of resistance so as to maintain the potency of the drugs currently in the therapeutic armamentarium.[1] In this context, the significant decline in the use of antibiotics in the United States in recent years is a good sign.[2]

CHOICE OF ANTIBIOTIC, DOSE, AND ADMINISTRATION SCHEDULE

As in all of clinical medicine, a thorough history and physical examination are central to proper decision making and to achieving optimal therapeutic outcomes in patients with infections. Key to choosing the correct drug, dose, and schedule of antibiotic administration is recognition that an infection exists. The next steps are to document where the infection exists, and then to identify the dominant organisms present at each site of infection. The final step is to determine whether any risk factors might predict the presence of drug-resistant pathogens.

As an example, it is known that community-associated pneumonia (Chapter 85) is caused by certain traditional bacterial pathogens. *Streptococcus pneumoniae* (Chapter 268), *Haemophilus influenzae* (Chapter 277), and *Moraxella catarrhalis* are among the classic bacterial pathogens associated with this entity (Table 266-1). "Atypical" pathogens such as *Legionella* species (Chapter 290), *Mycoplasma pneumoniae* (Chapter 293), and *Chlamydophila pneumoniae* (Chapter 294) also may be seen. In contrast, intra-abdominal infections are dominated by *Escherichia coli* (Chapter 280) and other Enterobacteriaceae (Chapter 281), and anaerobic organisms such as *Bacteroides* species. Consequently, it is important to understand the dominant pathogens present at different infection sites so that the best drug or combination of drugs can be chosen to treat the infection.

Knowing the site of infection is also critical because drugs penetrate differently into different body sites. Classically, penetration is poorer into spaces where there are tight junctions, such as the central nervous system, the eye, and the prostate. In general, the penetration of many classes of antibacterial agents is good into complicated skin and skin structure infection sites. What is often not appreciated is the divergent penetrations of different agents and even agents within the same class into the lung to treat bacterial pneumonia.

ABSTRACT

Antibiotics have improved human health, both in the treatment of established infections and as prophylaxis against infections associated with surgical and other invasive procedures. Factors for consideration in the selection of empirical single or combination antibiotic treatment include information gained from a history and physical examination, review of available imaging studies, and understanding the likely bacterial species that are in the site of infection, as well as the epidemiologic risk factors for the probability the infection is caused by multidrug-resistant bacteria. Consultation of hospital antibiograms of bacteria encountered in intensive care and other inpatient units is an important part of this framework. Also, for infections in normally sterile sites, a Gram stain may guide the choice of empirical antibiotic therapy. Adherence to pharmacokinetic and pharmacodynamic principles can help optimize the efficacy of antibiotics. Antibiotic susceptibility testing may enable narrowing of the spectrum of activity of the antibiotic regimen.

antibiotic resistance

For instance, the penetration by macrolide antibiotics into skin infection sites is modest, but their penetration into the lung is good, with penetration ratios (area under the concentration-time curve [AUC] in lung epithelial lining fluid/AUC in plasma) ranging from 4 to 20. The penetration of β-lactam drugs can range from 15 to 100%, but no set of variables explains such a range of penetrations.

It is also important to understand other factors that increase the probability that a resistant organism is present at the primary infection site. An example is a patient who has recently taken antibiotics before acquiring the present infection. Other examples are the acquisition of an infection in the hospital or in an extended care facility or a patient who is immunosuppressed. In such patients, the choice of antimicrobial agents must be careful to cover more resistant pathogens.

CULTURE AND GRAM STAIN

Once the site of infection has been definitively identified or the most likely source of infection has been determined, it is critical to obtain microbial specimens from that site as well as to obtain blood culture samples. Increasingly, molecular testing is available to provide rapid diagnosis of certain bacterial infections from some sites.[A1] Nevertheless, the correct performance and interpretation of a Gram stain remains an important component for the diagnosis of many infections. Even though it is usually not possible to make a definitive diagnosis on the basis of the cellular morphology of the organism, it is possible to combine information on the morphology, the organism's gram positivity or negativity, the site of the infection, and the most likely pathogens to make an initial antimicrobial choice with the highest probability of producing effective chemotherapy.

The initial antibiotic regimen chosen to cover organisms present at the primary infection site has a significant influence on the outcome of therapy, and such initial choices should always err on the side of caution. When the specific microorganism has been identified and even before antimicrobial susceptibility testing results are available, the chemotherapy usually can be streamlined.

SUSCEPTIBILITY

Because infections occur at a specific place, it is important to have an understanding of the local antimicrobial susceptibility patterns. Oftentimes, these susceptibility patterns are different even within the same hospital. For example, patients on a general inpatient unit are generally (but not always) infected with pathogens derived from the community setting, whereas patients in an intensive care unit (ICU) are more likely to have hospital-acquired infections. In severely infected patients, particularly patients whose infections were acquired in the ICU, infections are likely to be resistant to multiple antimicrobial agents.

Antimicrobial susceptibility testing[3] can determine the minimal inhibitory concentration (MIC), or can tell whether an organism is susceptible (S), intermediate (I), or resistant (R) to an antibiotic. The MIC is often misunderstood as the concentration of drug that prevents the pathogen from growing, but it is actually the concentration of drug that allows a tube (or well) containing the pathogen to remain clear by visual examination after 16 to 24 hours. This criterion can actually allow almost a 1 $\log_{10}$ (colony forming units [CFU]/mL) increase in bacterial count over this time frame and still be read as the MIC. With all its limitations, the MIC provides critical information about drug choice. For several infections, such as meningitis, endocarditis, and perhaps bacteremia, knowing the minimal bactericidal concentration (defined as the concentration required to kill 99.9% of organisms during 16 to 24 hours) is valuable. In these cases, it is important to obtain multi-log killing of the organism to ensure a high probability of a good clinical outcome. For meningitis and endocarditis, there is also the confounding problem of penetration of the drug into the primary infection site. In other circumstances (e.g., ventilator-associated pneumonia) in which bacterial burdens are high, optimizing the probability of cure requires highly bactericidal therapy.

TABLE 266-1 PRIMARY INFECTION SITES AND THE DOMINANT BACTERIAL SPECIES PRESENT

SITE	BACTERIA
Complicated skin or skin structure infection	*Staphylococcus aureus* and *Streptococcus* spp
Diabetic foot ulcer	Organisms above plus Enterobacteriaceae
Intra-abdominal infections	*Escherichia coli* and other Enterobacteriaceae plus anaerobes
Community-acquired bacterial pneumonia	*Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis*, "atypical" pathogens
Hospital-acquired pneumonia	*S. aureus, Klebsiella pneumoniae, Enterobacter* spp, *Pseudomonas aeruginosa, Acinetobacter* spp
Meningitis	*S. pneumoniae, H. influenzae* (nontypable), meningococci; in hospital settings, *S. aureus* and gram-negatives
Urinary tract infections	Enterobacteriaceae, particularly in sexually active women; multiresistant gram-negatives in patients with complicated urinary tract infections or those instrumented; enterococci, particularly in elderly men
Prostatitis	Enterobacteriaceae, enterococci, atypical pathogens

spp = species.

DETERMINING THE "CORRECT" DRUG DOSE

The correct drug dose is the one that produces a high likelihood of achieving a good clinical response with a low probability of causing a concentration-driven adverse event. Another consideration is that the optimal dose should have a high probability of suppressing the emergence of resistant mutants. Confidence that a drug dose has a high likelihood of producing a good clinical outcome requires an understanding of the relationship between drug exposure and outcome, i.e., pharmacodynamics (Chapter 25).

When a drug is administered intravenously or orally, the drug concentration starts low, increases to a maximal value, then declines over time until another dose of the drug is given (in a multidose regimen). This drug concentration–time profile should be seen relative to a measure of drug potency against the pathogen in question: the MIC (or minimal bactericidal concentration). Protein binding is also important because, in almost all cases, it is the free or non–protein-bound drug that kills the causative pathogen. So understanding the pharmacodynamics of a drug or class of agents first requires knowledge of the drug's concentration–time profile, protein binding, and MIC (Fig. 266-1). For drugs that kill organisms much faster as their concentrations rise (e.g., fluoroquinolones, aminoglycosides), the free drug AUC/MIC ratio is most closely linked to drug effect. For other drugs (e.g., penicillins, carbapenems, cephalosporins, monobactams), the rate of kill rises with the concentration and plateaus quickly, in which case the free drug time greater than MIC (T > MIC) is most closely linked to drug effect. On occasion, the free drug peak concentration/MIC ratio is linked to drug effect, as is seen when there is a rapid and frequent emergence of resistance, and the peak concentration helps suppress the amplification of resistant mutant subpopulations.

RESISTANCE

Antimicrobial resistance is a growing problem in both the hospital and outpatient settings.[4,5] If the drug is properly chosen, the organism should have a high probability of being susceptible to it. However, during the course of therapy, the organism has many mechanisms available to make it less susceptible (the MIC increases) to the administered drug, thereby making the drug less effective than was originally envisioned and resulting in a lower probability of cure.

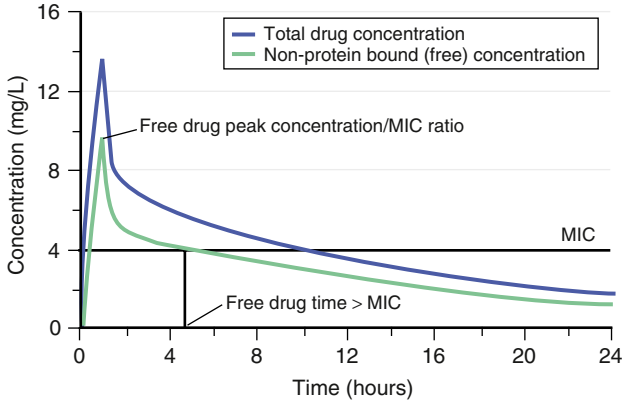

FIGURE 266-1. Three measures of drug exposure are important to the measure of potency, or the minimal inhibitory concentration (MIC). These measures are free drug peak concentration/MIC ratio, free drug time greater than MIC, and free drug area under the curve (AUC)/MIC ratio. AUC = area under the concentration-time curve.

TABLE 266-2 MECHANISMS OF ANTIMICROBIAL RESISTANCE

ANTIBACTERIAL AGENT	MECHANISM	REPRESENTATIVE ORGANISM
β-Lactams (penicillins, cephalosporins, carbapenems, aztreonam)	Altered target (penicillin-binding proteins)	Methicillin-resistant *Staphylococcus aureus* (MRSA), penicillin-resistant *Streptococcus pneumoniae, Enterococcus faecium*
	Reduced permeability	Enterobacter spp, *Pseudomonas aeruginosa, Acinetobacter* spp
	Enhanced efflux	*P. aeruginosa, Acinetobacter* spp
	β-Lactamases	*S. aureus*, Enterobacteriaceae (includes ESBLs), *Haemophilus influenzae, Moraxella catarrhalis , Neisseria gonorrhoeae, Enterococcus faecalis, P. aeruginosa, Acinetobacter* spp
Aminoglycosides	Inactivating enzymes (acetylation, adenylation, phosphorylation)	*S. aureus*, enterococci, *P. aeruginosa,* Enterobacteriaceae
	Reduced permeability	Enterobacteriaceae, *P. aeruginosa ,* enterococci
	Enhanced efflux	*P. aeruginosa*
	Decreased ribosomal binding	*S. aureus, E. faecalis,* mycobacteria (streptomycin), gram-negative pathogens (aminoglycoside ribosomal methylase)
Chloramphenicol	Enhanced efflux	*H. influenzae*
	Reduced permeability	Enterobacteriaceae
	Inactivating enzyme (acetylation)	*S. aureus, S. pneumoniae,* enterococci
Daptomycin	Altered target	*S. aureus*
Glycylcyclines	Enhanced efflux	Enterobacteriaceae, especially *Proteus*
Macrolides, clindamycin, ketolide, quinupristin	Altered target (methylation of ribosomal RNA)	*S. aureus, S. pneumoniae* (not ketolide), streptococci, *Bacteroides fragilis*
	Enhanced efflux (not clindamycin or ketolide)	*S. pneumoniae*, streptococci
	Reduced permeability	Enterobacteriaceae
	Inactivating enzymes	*Escherichia coli, Klebsiella pneumoniae, S. aureus*
Lefamulin	Altered target	*S. aureus, Mycoplasma* spp
Oxazolidinones	Altered target	Streptococci, enterococci, *S. aureus*
Quinolones	Altered target (DNA gyrase, topoisomerase IV)	Enterobacteriaceae, *P. aeruginosa*
	Reduced permeability	Enterobacteriaceae, *P. aeruginosa*
	Enhanced efflux	*E. coli, P. aeruginosa*
Tetracyclines	Altered target (ribosome)	*N. gonorrhoeae,* streptococci
	Enhanced efflux	*E. coli, S. pneumoniae*
	Reduced permeability	Enterobacteriaceae
	Drug inactivation	*B. fragilis*
Rifampin	Altered target (β-subunit of polymerase)	*E. coli, S. aureus, Mycobacterium tuberculosis*
Sulfonamides, trimethoprim	Altered target (dihydropteroate synthase or dihydrofolate reductase)	Enterobacteriaceae, *M. catarrhalis*
	Enhanced *p*-aminobenzoic acid production	*S. aureus, N. gonorrhoeae*
	Reduced permeability	*P. aeruginosa,* Enterobacteriaceae
Vancomycin and lipoglycopeptides	Altered target (peptidoglycan precursor binding site)	*E. faecium, E. faecalis, S. aureus*

ESBLs = extended-spectrum β-lactamases; spp = species.

MECHANISMS OF RESISTANCE

Five factors account for the majority of cases of resistance emerging during therapy (Table 266-2). The first is the mutational frequency to resistance of the organism being treated. Because mistakes are made by the organism during replication, mutations occur in the genome at a specific rate, which is organism-dependent. For antibiotic resistance, the mutational frequency rate is generally about 1 in 10^6 to 10^8 CFU. Some organisms, however—referred to as hypermutators—that have mutations in other parts of the genome that alter their DNA replication error–checking mechanisms. These organisms' mutational frequencies are generally 10- to 100-fold higher than those of organisms without such mutations.

The second factor is related to the bacterial burden. As the bacterial burden increases and ultimately surpasses the inverse of the mutational frequency to resistance, it becomes increasingly more likely that a preexistent antibiotic-resistant mutant already exists in the population. For example, if the mutational frequency to resistance is 1 resistant organism per 10^7 CFU and the patient has a bacterial infection in which the total bacterial burden is 10^9 organisms, it is highly likely that a resistant organism is present in the population a priori. Antibiotic pressure provides these mutants with a selective advantage; they are amplified, whereas the more susceptible bacteria are killed by the antibiotic. A calculation of the actual probability can be performed by a Poisson distribution, the bacterial burden, and the mutational frequency to resistance. Consequently, infections in which the bacterial burden is high are more likely to generate resistance during therapy. For example, in clinical trials of ventilator-associated pneumonia, single-agent β-lactam drugs or fluoroquinolones allow the emergence of antibiotic resistance during therapy 33 to 50% of the time.

The third issue is drug penetration. In some circumstances, such as an empyema, the bacterial burden is high, but the drug's penetration to the infection site is reduced. In this case the emergence of resistance is more likely. In contrast, poor penetration with relatively low bacterial burdens (e.g., meningitis) generally does not result in a high probability of the emergence of resistance.

The fourth issue has to do with error-prone replication in bacterial pathogens. When resistance develops relatively late in therapy and the bacterial burden is modest, error-prone replication is often to blame. Antibiotics differ greatly with respect to their ability to induce the bacterial isolate to perform error-prone replication. Perhaps the best example is the fluoroquinolone antimicrobials, because these drugs strike at the heart of DNA replication. The organism senses the attack of the antibiotic, and a cascade of events ensues, the most important of which is the induction of error-prone polymerases (e.g., pol V). These polymerases markedly increase the error rate in DNA replication. Most of these errors are lethal to the organism and therefore unhelpful to it. However, because this process is totally random, by chance a mutation can occur in a gene that provides protection from the onslaught of the antibiotic (e.g., a mutation in the DNA gyrase when the patient is receiving a fluoroquinolone). This selective replication advantage (emergence of resistance) results in an increase in the MIC of the mutant organism relative to the baseline organism.

The fifth factor relates to mechanisms other than antibacterial target site mutations that allow the organisms to survive in the face of appropriate antibiotic chemotherapy. One extremely common mechanism seen in the majority of both gram-positive and gram-negative organisms is the upregulation of efflux pumps. These pumps are indiscriminate in their ability to pump molecules; they can eject multiple classes of antibacterials from the organism as

well as other natural substances that can harm it, such as metal ions. These pumps keep drug concentrations at their target sites much lower than they would be in the absence of the pumps. The pumps can be induced and then downregulated once the threat has passed; or occasionally, the organism can have a mutation in the part of the genome where expression of the pump is regulated, so the pump is always expressed (constitutive expression).

A similar process is seen with the production of β-lactamases. Often, these enzymes are situated on plasmids and are produced continuously. Sometimes, as with the efflux pumps, the bacteria sense the β-lactam, and their β-lactamase production is markedly increased (the phenomenon of induction, seen with ampC-type enzymes, which generally reside on the chromosome). Sometimes, also like the pumps, the organisms have a mutation in the part of the genome that regulates production of the β-lactamase. This event is referred to as *stable de-repression,* and large quantities of the enzyme are made continuously. The enzyme hydrolyzes its substrate (the β-lactam drug), thereby preventing this antibiotic from binding to the target sites, the β-lactam–binding proteins.

Finally, in gram-negative organisms, the drug must cross the diffusional barrier of the outer membrane before binding to β-lactam–binding proteins (if the drug is a β-lactam) in the periplasm of the organism, or it must cross the inner membrane if its target site is actually inside the organism. For many agents, particularly those that are water soluble, a large percentage of their influx is due to passage through porin proteins. These proteins are water-filled channels that pass through the entirety of the outer membrane of gram-negative bacteria. Part of their function is to provide access to nutrients for the organism and allow the easy diffusion of waste products. These channels are also used to obtain passage by water-soluble antibacterial agents. The organism has the ability to downregulate these channels, either temporarily or permanently (by mutation). An example is *Pseudomonas aeruginosa* (Chapter 282), in which downregulation of the porin channel oprD markedly diminishes the penetration of carbapenem antibiotics (β-lactam agents), with a resultant two- to eight-fold rise in MIC.

These mechanisms also interact. In most cases, resistance is caused by an alteration in the target site; by an enzyme that alters the drug, thereby resulting in a lack of activity; by the drug's being pumped out of the organism; or, in the case of gram-negative pathogens, by the loss or downregulation of a transmembrane porin protein. These mechanisms, along with error-prone replication, can interact to cause large increases in the MIC. For example, a gram-negative pathogen that acquired a mutation in its gyrase enzyme would generally have only a four-fold increase in its MIC value for a fluoroquinolone antimicrobial; however, if this isolate also had an efflux pump upregulated, the MIC could change 8- to 16-fold. In the case of fluoroquinolone antimicrobials, where error-prone replication almost always occurs under pressure, the upregulation of efflux pumps relieves some of the antibiotic pressure, thereby allowing the organisms to undergo more rounds of replication per unit of time, giving the error-prone replication mechanism more time to find a mutation that is not lethal, and providing protection against the drug at the primary target site.

With all the mechanisms that can be brought to bear, it is not surprising that poor dosing and prolonged courses of therapy often lead to the emergence of resistance.

SUPPRESSING THE EMERGENCE OF RESISTANCE

Suppressing the emergence of resistance is an end point that is different from achieving a good clinical or microbiologic outcome. The antimicrobial exposure (free drug peak concentration/MIC ratio, free drug AUC/MIC ratio, or free drug time greater than MIC) necessary to suppress resistance is always at least as high as that required to attain maximal killing of bacterial cells; and in many instances, it is substantially higher.

Fortunately, it is possible to identify drug doses and administration schedules that suppress the emergence of resistance as well as provide optimal killing of bacterial cells. Unfortunately, many of the exposures necessary to achieve such an outcome are high enough to increase the probability of drug toxicity.

The other way to help suppress the emergence of resistance is to employ combination chemotherapy. Combination therapy has major advantages but significant disadvantages as well. Among the advantages are that combination therapy can improve the spectrum of coverage in the setting of empirical treatment as well as help suppress the emergence of resistance. This phenomenon is best seen in the treatment of *Mycobacterium tuberculosis* (Chapter 299), although there is growing evidence that this may also be true for difficult-to-treat pathogens such as *P. aeruginosa* (Chapter 282) and *Acinetobacter* (Chapter 283) species. Combination therapy can be effective against some pathogens in serious infections for which a single agent would not be adequate. Enterococcal endocarditis (Chapters 61 and 270) is the classic example; ampicillin or vancomycin is generally static and not up to the task of curing this disease, and the second agent (an aminoglycoside, streptomycin, or gentamicin) is somewhat resistant when it is used alone (MIC values <500 mg/L). Yet the combination produces excellent bacterial cell killing in the endocarditic vegetation, with a high probability of cure if the patient can tolerate the combination for the requisite time.

The disadvantages of combination therapy are also well known. At full doses of each, there may be added toxicity and there are certainly greater costs associated with combinations. Finally, combinations of agents may interact antagonistically instead of either additively or synergistically. For example, the combination of tetracycline plus penicillin is somewhat antagonistic and should be avoided. However, there are circumstances in which weak antagonism is tolerable. For instance, the combination of isoniazid plus rifampin, part of the standard therapy for *M. tuberculosis* (Chapter 299), is somewhat antagonistic with respect to cell killing, but the combination provides superb protection against the emergence of resistance.

MECHANISM OF ACTION

The search for new antimicrobials begins with the principle that the target that affects pathogens must not be in the human genome or must be sufficiently different that the agent in question does not cause appreciable human toxicity (Table 266-3). β-Lactam antibiotics are a good example: the inhibition of peptidoglycan synthesis has no effect on humans because this target is simply not present. An example of differing susceptibility to inhibition because of poor sequence homology between bacteria and humans can be seen in the inhibitors of the bacterial ribosome. The bacterial ribosome is much smaller than that in humans and has differing affinities for such drugs as aminoglycosides, tetracyclines, macrolides, and clindamycin. Consequently, such agents are an important part of the therapeutic armamentarium and cause only minor adverse effects related to their primary mode of action. In some cases, so-called off-target toxicity may take place. Again, an example is the β-lactams; a major toxicity is accelerated allergic reaction, even though the target for the agents is not present in humans.

Often, antimicrobials are thought of as either *bacteriostatic* or *bactericidal,* for which there are standard definitions. An agent that causes a 1000-fold decline (3 $\log_{10}$ [CFU/mL] decrease) in an in vitro test system during 18 to 24 hours is defined as being bactericidal. Any agent that causes a smaller decline is defined as bacteriostatic. Although these definitions are arbitrary, there is a clinical connection. Bacteriostatic and bactericidal antibiotics are equivalently effective for abdominal infections, skin and soft tissue infections, and pneumonia,[6] but data are not sufficient for meningitis, endocarditis, or patients who are neutropenic.[A2] Obviously, the more organisms the antimicrobial kills, the easier it is to accomplish cure. In other circumstances, such as multilobar pneumonia, it is critical to kill as many of the organisms as possible so as not to overwhelm the body's immunologic defenses. For these reasons, clinicians generally prefer bactericidal to bacteriostatic agents.

EFFECTS OF PHARMACOKINETIC CHANGES

Whereas antimicrobial pharmacodynamics is the study of the effect of a drug on an infecting organism, pharmacokinetics is the study of the effect of the body's processes on the drug concentration–time profile and the drug's ability to penetrate to the site of the infection (or the site of toxicity). A drug's pharmacokinetics are prime determinants of whether a drug will be able to kill or to inhibit the offending pathogen and, because many toxicities are concentration related, whether a serious drug-related toxicity will occur.

Each antimicrobial has an appropriate administration schedule (Table 266-4) that considers its antimicrobial activity, protein-binding ability, and whether alterations in renal or hepatic function cause major changes in its concentration-time profile. As in all chemotherapy, the aim is to achieve a concentration-time profile in the plasma and at the infection site sufficient to inhibit or to kill the pathogen without causing toxicity. In some situations, continuous infusion may be preferable to intermittent dosing to maintain therapeutic drug levels.[A3]

Although it is almost always possible to provide a reliable guide to the concentration–time profile that results in an appropriate antimicrobial effect, it is more difficult to identify a linkage between drug exposure and the occurrence of toxicity. For the aminoglycosides, the exposure-efficacy and exposure-nephrotoxicity relationships show that higher aminoglycoside AUC exposures increase the probability of treatment efficacy and drug toxicity

TABLE 266-3 MECHANISMS OF ACTION OF ANTIMICROBIAL AGENTS

AGENT	SITE OF ACTION	EFFECT	BACTERICIDAL	BACTERIOSTATIC
β-Lactams (penicillins, cephalosporins, carbapenems, aztreonam)	Cell wall: penicillin-binding proteins	Inhibit cross-linking of peptidoglycan (transpeptidation), impair cell wall synthesis	+	Occasionally (enterococci)
Vancomycin, teicoplanin, dalbavancin, telavancin, oritavancin	Cell wall: terminal D-alanyl-D-alanine of pentapeptide peptidoglycan precursor	Inhibit polymerization of disaccharide precursors to peptidoglycan (transglycosylation), impair cell wall synthesis	+	Occasionally (enterococci)
Daptomycin	Cell membrane	Rapid depolarization of membrane potential	+	Occasionally (enterococci)
Aminoglycosides	Protein synthesis: 30 S ribosome subunit	Inhibit peptide elongation, cause misreading of genetic code, inhibit protein synthesis	+	
Tetracyclines, glycylcyclines	Protein synthesis: 30 S ribosome subunit	Inhibit binding of transfer RNA, inhibit protein synthesis	Occasionally	+
Chloramphenicol	Protein synthesis: 30 S ribosome subunit	Blocks attachment of aminoacyl transfer RNA, inhibits protein synthesis	Occasionally	+
Macrolides, azalides, ketolides	Protein synthesis: 50 S ribosome subunit	Block transfer of amino acids to peptide chain, inhibit protein synthesis	Occasionally	+
Clindamycin	Protein synthesis: 50 S ribosome subunit	Blocks transfer of amino acids to peptide chain, inhibits protein synthesis	Occasionally	+
Quinupristin-dalfopristin	Protein synthesis: 50 S ribosome subunit	Block extrusion of peptide chains, inhibit protein synthesis	+	+ (with quinupristin resistance)
Linezolid and tedizolid	Protein synthesis: 50 S ribosome subunit	Blocks formation of 70 S initiation complex, inhibits protein synthesis	Occasionally	+
Rifampin	Nucleic acid synthesis: β-subunit of DNA-dependent RNA polymerase	Inhibits RNA synthesis	+	
Metronidazole	Nucleic acid synthesis	Damages nucleic acids, inhibits DNA synthesis	+	
Quinolones	Nucleic acid synthesis: DNA gyrase, topoisomerase IV	Impair supercoiling of DNA, prevent decatenation of DNA molecules after replication, inhibit DNA synthesis	+	
Sulfonamides	Folic acid synthesis: dihydropteroate synthase	Competitive inhibition of synthesis of dihydrofolate from *p*-aminobenzoic acid, pteroate, and glutamic acid	Occasionally (when used with trimethoprim)	+
Trimethoprim	Folic acid synthesis: dihydrofolate reductase	Inhibits reduction of dihydrofolate to tetrahydrofolic acid	Occasionally (when used with sulfonamide)	+
Lefamulin	Protein synthesis: 50 S ribosome subunit	Inhibits binding of transfer RNA, inhibit protein synthesis	Occasionally (microbe specific)	+ (*S. aureus*, *S. pyogenes*)

TABLE 266-4 DOSAGE REGIMENS OF ANTIBACTERIALS, PHARMACOKINETICS, AND DOSE ADJUSTMENT IN PATIENTS WITH RENAL OR HEPATIC FAILURE

CLASS/AGENT	DOSE* FOR SYSTEMIC INFECTION	ORAL FORMULATION	PEAK SERUM CONCENTRATION (μg/mL)	PROTEIN BINDING (%)	NORMAL SERUM HALF-LIFE (hr)	HEPATIC FAILURE	RENAL FAILURE	SERUM LEVELS ALTERED BY DIALYSIS

**Oral vancomycin is not absorbed; it is used for intraluminal therapy only.
H = hemodialysis; P = peritoneal dialysis; PO = orally; STI = sexually transmitted infection.

(Fig. 266-2A). Importantly, increased aminoglycoside exposures may be required to optimize the treatment effect for bacteria that have increased MICs for the antibiotic. The higher drug exposures may also increase the probability of drug toxicity (Fig. 266-2A through 266-2C). The evaluation in the figure is based on twice-daily dosing; summing the milligrams of aminoglycoside in the twice-daily dosed regimen and administering that amount once daily markedly decreases the probability of nephrotoxicity by increasing the time for aminoglycoside that are enters the renal tubular cells to leave these cells between doses.

When no toxicity relationship is available, there is still a drug exposure target for good clinical effect. Achievement of this target should be paramount, and alterations for renal or hepatic impairment should strive to maintain the same high likelihood of effect that is seen in patients who have relatively normal clearance function. The options are to change the dose or to change the schedule of administration to decrease the drug's accumulation in the presence of renal or hepatic impairment (depending on the drug) and then recalculate the impact on the likelihood of attaining a good clinical outcome. For the increase in exposure relative to that in patients with normal clearance, a certain maximal amount of increased accumulation may be acceptable, provided that the dose adjustment maintains a high likelihood of a good overall outcome, considering both efficacy and toxicity. The acceptability of the increased drug exposure after dosage adjustment is usually based on a combination of preclinical and clinical toxicology data, but the overarching issue is that the proposed dose or schedule alteration must maintain a high probability of a good clinical outcome.

DRUG CLASSES AND THEIR PROPERTIES

Antimicrobial drug classes differ in their mechanisms of action, mechanisms of emergence of resistance, and whether they kill substantial numbers of organisms or only inhibit bacterial growth.

β-LACTAM AGENTS

The β-lactams include the penicillins, cephalosporins, monobactams, and carbapenems. This class of drugs is arguably the most important group of antimicrobials.[7,8] With chemical modification, they have an exceptionally broad spectrum of activity and, in general, an excellent safety profile. The major toxicity is related to allergic reactions to a degradation product of the drug.

These agents bind to their targets, bacterial β-lactam–binding proteins (also called penicillin-binding proteins). These binding proteins have an active site serine, and the drug forms a covalent bond with this site through the carbonyl of the β-lactam ring. Sometimes, the binding has direct effects on the organism's shape. For example, in gram-negative organisms, binding to penicillin-binding protein (PBP)-2 causes the organism to assume a spherical shape, whereas binding to PBP-3 causes the formation of long chains of organisms. In general, high-affinity binding to PBP-1 leads to the rapid death of the organism, sometimes accompanied by lysis. The classic response of *S. pneumoniae* (Chapter 282) to penicillin G is rapid lysis of the organism. Binding to PBP-1 (1a or 1b) leads to activation of *N*-acetylmuramic acid amidase, which destroys the bacterial cell wall, resulting in lysis.

The most common way for pathogens to protect themselves from β-lactams is by elaborating β-lactamases. The genes for these enzymes may be on plasmids or other bits of transmissible DNA, or they may reside on the bacterial chromosome. Some drugs, such as the carbapenems, are resistant to hydrolysis by many enzymes (but certainly not all of them, especially the metallo-β-lactamases and *K. pneumoniae* carbapenemase-type β-lactamases). The activity of β-lactams may be protected by administering these drugs in combination with a β-lactamase inhibitor. Examples include potassium clavulanate, sulbactam, tazobactam, and, most recently, avibactam, relebactam, and vaborbactam. These agents inhibit different types of β-lactamases, but only avibactams inhibit the ampC-type enzymes carried by *P. aeruginosa* (Chapter 282), *Enterobacter* species (Chapter 281), *Citrobacter* species (Chapter 281), *Serratia marcescens,* and indole-positive *Protea* (SPICE organisms).

All β-lactams are relatively nonconcentration-dependent in their kill rate, and free (nonprotein bound) drug time greater than MIC (T > MIC) is the pharmacodynamic index linked with increased organism killing. The classes differ somewhat, with carbapenems requiring approximately 40% free drug T > MIC for near-maximal bacterial killing. For penicillins, this percentage is approximately 50%, and for cephalosporins and monobactams, it is 60 to 70%. When these agents need to penetrate to a site of infection, such as the fluid that covers the alveolar cells or the central nervous system, the pharmacodynamic target values may change.

AMINOGLYCOSIDES

Aminoglycosides are important components of combination regimens for seriously ill patients, particularly in the empirical therapy setting for patients thought to be infected by gram-negative organisms.[9] Naturally occurring aminoglycosides include kanamycin, neomycin, gentamicin (actually a combination of three congeners), and tobramycin. Other semisynthetic agents, such as amikacin, netilmicin, and arbekacin (among others), have been synthesized.

Nephrotoxicity and middle ear toxicity (hearing loss or loss of balance) are the dose-limiting toxicities of aminoglycosides. However, most (but not all) of the nephrotoxic potential can be ameliorated by intermittent dosing of these drugs (usually once daily). Even with daily therapy, however, prolonged use can still result in nephrotoxicity or ototoxicity.

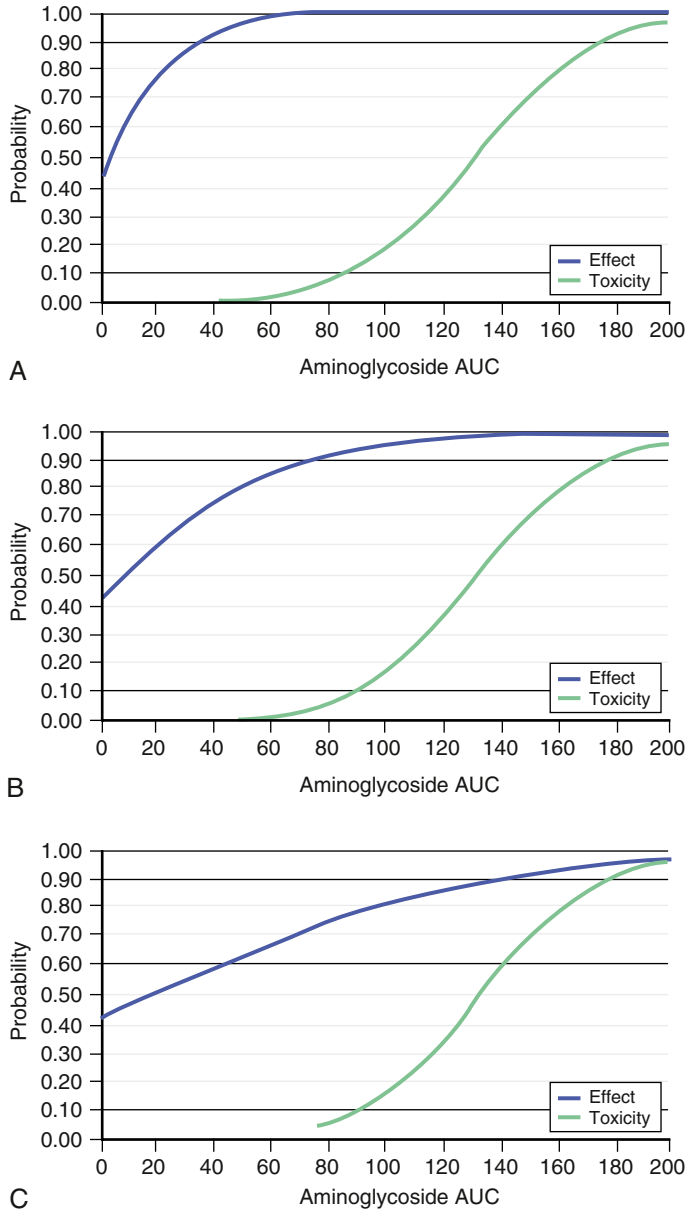

FIGURE 266-2. Probability of successful clinical effect and nephrotoxicity as a function of aminoglycoside area under the curve (AUC) for infections caused by microbes with different MICs to an aminoglycoside. A, Minimal inhibitory concentration (MIC) = 0.25 mg/L. **B,** MIC = 0.5 mg/L. **C,** MIC = 1.0 mg/L.

The recent rise in resistance, particularly among gram-negative bacteria, and new mechanisms mediating resistance even to the best β-lactam agents have resulted in renewed interest in existing aminoglycosides and a search for new ones that are more resistant to inactivation by the aminoglycoside-modifying enzymes. Plazomicin, which is a newer parenteral aminoglycoside that targets Enterobacteriaceae (Chapter 281),[10] is approved for the treatment of complicated urinary tract infections. Due to structural modifications, plazomicin remains active against many resistance mechanisms that render bacteria resistant to the other aminoglycosides.

Aminoglycosides are concentration-dependent in terms of their bacterial killing and are rapid killers. Hence, the AUC/MIC ratio (or, as sometimes reported, peak concentration/MIC ratio) is the pharmacodynamic index that is most closely associated with bacterial killing. Therefore large doses administered daily to patients with normal renal function optimize bacterial killing, as well as minimizing nephrotoxicity.

The older aminoglycosides (streptomycin and gentamicin) have the best profile for synergizing with drugs that are active against gram-positive streptococci (particularly enterococci). Tobramycin generally has the most potent activity against *P. aeruginosa* (Chapter 282) (depending on the aminoglycoside-modifying enzymes present in a specific locale), and less resistance is generally seen with amikacin (again, depending on the locale). Streptomycin and amikacin, because of the number of amino groups they carry, are usually about four-fold less potent than gentamicin or tobramycin. Consequently, their dosages are approximately three- to four-fold higher.

QUINOLONES

Quinolones are completely synthetic and do not exist in nature. They are inhibitors (depending on the drug and the organism) of topoisomerases II and IV to block DNA replication, thereby making them rapidly bactericidal. A fluorine substitution markedly enhances the microbiologic activity of these drugs, thereby making them useful for treating both community-associated infections (especially urinary tract infections and pneumonia) as well as hospital-associated gram-negative infections.

These drugs penetrate well into most body spaces and accumulate within mammalian cells, so they are active against obligate intracellular pathogens such as *Chlamydophila* (Chapter 294), *Legionella* (Chapter 290), and *Mycoplasma* (Chapter 293).[11] They also penetrate well into body spaces with tight junctions (prostate, eye, central nervous system) and into the epithelial lining fluid of the lung.

Typically, the toxicities of these drugs are "off target." Several quinolones were withdrawn from the marketplace or given black box warnings by health authorities because of the infrequent occurrence of tendon rupture, torsades de pointes (Chapter 53), or other serious and life-threatening toxicities, such as eosinophilic hepatitis. Black box warnings now include hypoglycemia that may lead to coma and mental disturbances, including memory impairment and delirium. As a result, the U.S. Food and Drug Administration advises that the side effects of fluoroquinolones outweigh their benefits when patients with uncomplicated urinary tract infections (Chapter 263) and acute sinusitis (Chapter 394) have other options.

Quinolones are concentration-dependent bacterial killers, thereby indicating that the free drug AUC/MIC ratio is best associated with a regimen's ability to kill bacteria. Of interest, particularly for a drug that is completely synthetic, are a number of resistance mechanisms that allow bacteria to escape from drug pressure. The combination of efflux pump overexpression and error-prone replication, which results in target site mutants, as well as serious underdosing, has resulted in the emergence of considerable resistance, particularly among gram-negative isolates and in the ICU setting.

MACROLIDES, TETRACYCLINES, KETOLIDES, CLINDAMYCIN, AND OXAZOLIDINONES

These agents bind to different places in the bacterial ribosome, thereby making them inhibitors of protein synthesis and, for the most part, drugs with limited bactericidal activity. An exception may be their activity against *S. pneumoniae* (Chapter 268).

Macrolides (particularly clarithromycin and azithromycin) are most useful for community-acquired respiratory tract infections, for two reasons. First, their spectrum is well suited to the classic and atypical bacteria encountered in these patients.[12] Second, they concentrate well in lung epithelial lining fluid, with an accumulation that ranges from 6-fold to almost 20-fold of that in plasma. This accumulation partially explains why these agents have fared much better in the respiratory tract setting than in the skin and skin structure setting. Telithromycin, a ketolide, retains activity against many (but not all) macrolide-resistant isolates.

The macrolides and telithromycin are free drug AUC/MIC ratio–driven drugs with respect to bacterial activity, but for different reasons. Telithromycin is somewhat concentration-dependent with regard to its microbiologic activity, whereas classic macrolides are not. Telithromycin is more like aminoglycosides or quinolones in terms of the association between exposure indices and bacterial effect. Classic macrolides, especially azithromycin, induce a long persistent or post-antibiotic effect and are *not* concentration dependent in their bacterial effect. This post-antibiotic effect suppresses bacterial regrowth after the drug concentration declines below the MIC until the next dose of drug is administered. In this way, the linkage appears to be driven by the free drug AUC/MIC ratio but with a mechanism different from that of agents whose bacterial kill rate is concentration-dependent.

Most of the toxicities seen of these drugs are off target and gastrointestinal, including antibiotic-associated diarrhea and the more serious *Clostridioides difficile* colitis. There is also some prolongation of the QT interval (Chapter 42), which presumably explains why azithromycin has been considered to carry an increased risk of ventricular arrhythmia. However, a recent systematic review and meta-analysis of the cardiovascular safety of macrolides reported no statistical association with arrhythmia or cardiovascular mortality.[13]

Tetracyclines have an exceptionally broad spectrum of activity, including both gram-positive and gram-negative pathogens, and they are active against atypical pathogens. The latest incarnation of a tetracycline-type agent (tigecycline, a glycylcycline) has good activity against methicillin-resistant *S. aureus* (MRSA) as well. Tigecycline differs from previous tetracyclines (e.g., doxycycline, minocycline) in that its structure prevents many efflux pumps from removing the drug from the bacteria and also provides a degree of ribosomal protection.

The lincosamide antibiotic clindamycin has a spectrum that covers most clinically significant anaerobic bacteria, including many in the *Bacteroides* group (Chapter 273), although some resistance is being seen. It is thus a useful agent for infections in which anaerobes play a prominent role, such as lung abscesses and intra-abdominal infections. In many areas of the country, clindamycin has retained activity against methicillin-resistant *Staphylococcus aureus* (MRSA) (Chapter 267), but this should be verified with a D-test (inducible macrolide-lincosamide-streptogramin resistance) in the microbiology laboratory. It also has good activity against many streptococci (Chapter 269). Because it is a protein synthesis inhibitor, it may provide improved results when the staphylococcal or streptococcal isolate elaborates toxins.

Linezolid and tedizolid, which are members of the oxazolidinone class of antibiotics, are inhibitors of protein synthesis. They have excellent gram-positive activity, including robust activity against MRSA (Chapter 267). Oxazolidinones penetrate well into skin as well as into the epithelial lining fluid. They are prescribed to treat skin and skin structure infections, and currently only linezolid is licensed for treating streptococcal and staphylococcal (including MRSA) community-associated and nosocomial pneumonia. Intravenous and oral formulations are available for both drugs, and both drugs have high oral bioavailabilities.

The free drug AUC/MIC ratio is the pharmacodynamic index most associated with cell killing for the oxazolidinones. Bone marrow toxicity, including thrombocytopenia, neutropenia, and anemia, is linked to the dose and duration of oxazolidinone therapy. Lactic acidosis, peripheral neuropathy, and optic neuritis have been reported. Resistance occurs rarely and is seen with enterococci more frequently than with *S. aureus*.

VANCOMYCIN, QUINUPRISTIN-DALFOPRISTIN, DAPTOMYCIN, AND LIPOGLYCOPEPTIDES

Although structured differently, these agents (along with the oxazolidinones) are distinguished by having activity against many gram-positive bacteria, including MRSA (Chapter 267). Vancomycin acts at the cell wall and alters cell membrane permeability. It is bactericidal. The free drug AUC/MIC ratio is the driver of antimicrobial effect. This glycopeptide drug has activity against many gram-positive pathogens and is active against *C. difficile* (Chapter 271) when it is administered orally. As with most drugs, wide use has caused the emergence of vancomycin resistance in both enterococci and *S. aureus*.

Although vancomycin has a reputation for being a somewhat slow killer, no new agent has significantly outperformed it, at least in trials of skin and skin structure infections. MIC creep, in which an increase in vancomycin MICs in *S. aureus* is reported in a geographic region in serial surveillance studies over time, has been documented. Although many *S. aureus* isolates were once susceptible with MIC values of 0.25 and 0.5 mg/L, these are now in the distinct minority; 1.0 mg/L represents the modal value, with a few isolates having values of 2.0 mg/L. The higher MICs make these isolates more difficult to treat reliably with standard dosing (1 g IV every 12 hours). Also, it has recently become clear that higher vancomycin doses are associated with a significantly higher risk of nephrotoxicity, even when the agent is administered alone. In addition to nephrotoxicity, vancomycin causes histamine release ("red man syndrome") when it is administered too quickly intravenously. Infusion times of approximately 1 hour are recommended for standard doses.

Oritavancin, dalbavancin, and telavancin, which are semisynthetic lipoglycopeptide derivatives of vancomycin, kill streptococci, enterococci, and staphylococci (including MRSA) in a concentration-dependent manner by the same mechanisms of action as vancomycin. They are licensed for treating skin and skin structure infections due to these microbes. Oritavancin and dalbavancin have long terminal half-lives, and a single dose is given for treating these infections. Telavancin has an 8-hour serum half-life and is dosed once daily. These drugs are not used for the treatment of *C. difficile* colitis.

Quinupristin-dalfopristin is a combination of streptogramin A and streptogramin B antibiotics. Although each individual component is bacteriostatic, the combination can produce some cell killing because the two drugs are synergistic. The synergy is lost, however, with the emergence of resistance to either drug. Further, the amount of bacterial cell killing is modest because of the drugs' rapid half-lives and the imposition of a 12-hour dosing interval. This combination product has activity against resistant enterococci (Chapter 270) as well as MRSA (Chapter 267). Its toxicity includes relatively severe muscle pain in some patients. It is also phlebitogenic and has to be administered with a central venous catheter, limiting its utility.

Daptomycin is a cyclic lipopeptide antibiotic that is effective against MRSA, as driven by its free drug AUC/MIC ratio.

This agent has been licensed for skin and skin structure infections and, of note, for complicated *S. aureus* bacteremia (Chapter 267) and right-sided endocarditis (Chapter 61). It also has activity against enterococci (Chapter 270). The drug is bound up in epithelial lining fluid by surfactant, excluding its use in the therapy for pneumonia.

Daptomycin may cause muscle toxicity, which is rare, but this may be preceded by the harbinger of an elevated creatine kinase level. The muscle damage is driven by daptomycin trough concentrations, generally above a concentration of about 25 mg/L, and can be ameliorated by once-daily dosing to minimize trough concentrations. Monitoring of creatine kinase concentration is useful in the management of patients receiving daptomycin therapy.

TOXICITIES

All antimicrobials have toxicities, which vary among and even within classes (Table 266-5).

DURATION OF THERAPY

Relatively little is known about the optimal duration of therapy for specific infections treated with specific antimicrobial agents. Shorter courses of chemotherapy are preferred, if they are effective so as to minimize side effects and costs.[14]

For trimethoprim-sulfamethoxazole and fluoroquinolones, controlled trials have shown that 3 days of therapy is adequate for uncomplicated urinary tract infections in women (Chapter 263), and 7 days is as good as 14 days in afebrile men.[A4] Gonorrhea (Chapter 275) is highly likely to be cured by a single dose of drug (ceftriaxone, cefixime, fluoroquinolones) if the organism is susceptible to the drug.

In community-acquired pneumonia (Chapter 85),[A5] controlled trials have demonstrated optimal results with 5 days of therapy. For bacterial sinusitis (Chapter 394), direct sampling from the infected sinus has demonstrated that bacterial pathogens were eradicated by day 3 of therapy or earlier, particularly for *S. pneumoniae* infections. In ventilator-associated pneumonia, a double-blind comparison of 8 versus 15 days of therapy demonstrated that, with a single exception, clinical outcomes were just as good, with less emergence of resistance, fewer antibiotics administered, and less toxicity with 8 days of therapy. The single exception was when a nonfermenting gram-negative rod was cultured (*P. aeruginosa* or *Acinetobacter* species). In this circumstance, there were significantly more relapses with 8-day versus 15-day treatment, but clinical outcomes were similar. For hospitalized patients who have gram-negative bacteremia and clinical stability before day 7, a 7-day course of antibiotics is as good as 14 days.[A6]

In some infections, the organisms are slow growing and require more time for control. For example, 2 weeks of antibiotics are as good as 4 weeks after surgical drainage of native joint nongonococcal septic arthritis,[A7] but 12 weeks of antibiotic therapy is better than 6 weeks after appropriate surgical intervention in prosthetic valve endocarditis.[A8] Even when prolonged courses of antibiotics are required, however, a shift from parenteral to oral antibiotics should be made as soon as it is safe to do so.[A9]

One of the longest durations of therapy is seen in the treatment of tuberculosis. In this case some organisms are in the "nonreplicative persister" state, thereby indicating that they are not growing or metabolically active. When recovered, they are still fully susceptible to the antimicrobials being used, but while in this state, they are not readily killed with current chemotherapy (phenotypic, not genotypic, resistance). Durations of therapy are protracted, especially for relatively resistant organisms. Even with multidrug-resistant tuberculosis, however, a combination using pretomanid, bedaquiline, and linezolid can reduce the necessary duration of treatment for multidrug-resistant tuberculosis from 18 to 24 months to 6 months.[A10]

FAILURE OF ANTIMICROBIAL THERAPY

Antimicrobial therapy occasionally fails, with failure defined as the persistence of signs and symptoms of infection or the persistence of fever. In the face of apparent failure after what was thought to be adequate antimicrobial therapy, the clinician should rapidly pursue a series of possibilities. Did resistance truly emerge, or did superinfection occur? Is there an obstructed hollow viscus (e.g.,

TABLE 266-5 DIVERSE TOXICITIES OF ANTIMICROBIAL AGENTS

AGENT	GENERAL	SKIN	GI TRACT	BLOOD CELLS	KIDNEY	NERVOUS SYSTEM	OTHER
Penicillins	Hypersensitivity, anaphylaxis, serum sickness	Rash, urticaria, erythema multiforme	Diarrhea (ampicillin, amoxicillin-clavulanate), hepatitis (oxacillin)	Coombs-positive hemolytic anemia, impaired platelet function (ticarcillin), leukopenia, thrombocytopenia	Nephritis (methicillin), hypokalemia (carboxy- and ureido-penicillins)	Seizures, twitching (high doses, renal failure)	Inactivates aminoglycosides when admixed; possible with concurrent therapy in renal failure
Cephalosporins	Serum sickness (cefaclor), hypersensitivity, anaphylaxis (rare)	Rash, urticaria	Diarrhea, hepatic dysfunction, precipitates in bile (ceftriaxone), mild increase in LFTs	Neutropenia, increased prothrombin time, bleeding (due to MTT side chain), positive Coombs test	Enhances aminoglycoside toxicity, acute renal failure (rare), interstitial nephritis		Disulfiram-like reaction with alcohol use (MTT side chain)
Carbapenems	Hypersensitivity	Rash, urticaria, erythema multiforme	Vomiting with rapid infusion (imipenem), abnormal LFTs	Bone marrow suppression, positive Coombs test	Renal dysfunction	Seizures, myoclonus	
Aminoglycosides	Fever	Rash			Reversible renal failure	Irreversible vestibular toxicity and/or auditory damage, muscle blockade (with anesthetics and myasthenia gravis)	
Vancomycin and lipoglycopeptides	Allergy, fever	Rash		Leukopenia, thrombocytopenia	Nephrotoxic	Decreased hearing, neuropathy	Histamine release with flushing and hypotension (infusion <1 hr, antihistamines can prevent)
Quinolones	Headache, allergy, anaphylaxis (rare)	Rash (gemifloxacin), urticaria, photosensitivity (lomefloxacin)	GI distress, abnormal LFTs			Dizziness, insomnia, nervousness, tremors, visual changes, seizures	Tendon rupture; arthropathy in young animals
Sulfonamides	Hypersensitivity, anaphylaxis, serum sickness, fever	Rash, Stevens-Johnson syndrome, photosensitivity	Hepatitis	Hemolysis (G6PD deficiency), agranulocytosis, marrow suppression	Crystalluria	Neuropathy	Vasculitis
Trimethoprim ± sulfamethoxazole	Fever	Rash, erythema multiforme, Stevens-Johnson syndrome, TEN	Hepatitis, pancreatitis	Marrow suppression	Hyperkalemia, acute renal failure		
Chloramphenicol	Fever			Marrow suppression (dose related), aplastic anemia	Optic neuritis, neuropathy	Circulatory collapse (gray baby syndrome in neonates)	
Tetracyclines	Hypersensitivity	Photosensitization (doxycycline)	GI discomfort, hepatotoxicity in azotemia or pregnancy		Antianabolic aggravation of azotemia (except doxycycline)	Vertigo (minocycline)	Deposition in bone (dysplasia) and teeth (staining)
Macrolides	Fever	Rash	GI discomfort			Reversible decreased hearing	Phlebitis (IV erythromycin), metallic taste (clarithromycin)
Clindamycin	Fever	Rash	Diarrhea, pseudomembranous colitis				
Metronidazole	Headache, hypersensitivity		Nausea, metallic taste, pancreatitis	Leukopenia		Peripheral neuropathy, ataxia	Mutagenic, carcinogenic in rodents, disulfiram-like reaction with alcohol
Lefamulin	Headache		Nausea, diarrhea				Possible prolonged Q-T interval with underlying cardiac condition or when used with certain drugs

GI = gastrointestinal; G6PD = glucose-6-phosphate dehydrogenase; IV = intravenous; LFT = liver function test; MTT = methylthiotetrazole; TEN = toxic epidermal necrolysis.

urinary or gastrointestinal tract)? Is there an undrained abscess or infected collection (e.g., empyema)? Is there an infected foreign body (e.g., intravenous catheter or prosthesis), or is there devitalized tissue (e.g., sequestrum in osteomyelitis)? Is the fever (if present) attributable to a reaction to the drug being administered (Chapter 234)? Thoughtful examination of each of these possibilities can help guide the next steps.
